Attention: Mr. Charles A. Alders

Gentlemen:

Our draft "Report of Preliminary Geotechnical Investigation, Proposed Playa Vista Marina, Playa Vista Development - Parcel A, Lincoln Boulevard and Ballona Creek, Los Angeles County, California, for Howard Hughes Properties" is herewith submitted.

The report is being submitted in draft form so that comments and suggestions may be incorporated in the final submittal. We will be pleased to discuss the draft with you at your convenience.

Respectfully submitted,

LeROY CRANDALL AND ASSOCIATES

Attention: Mr. Joel Stensby
Vice President

Gentlemen:

Report of Preliminary Geotechnical Investigation
Proposed Marina
Playa Vista Project - Parcel A
Lincoln Boulevard and Ballona Creek
Los Angeles County, California

This letter transmits our prior report of preliminary geotechnical investigation for the proposed marina. That report, which is dated April 4, 1988 (AE-88473), was performed for Howard Hughes Properties and was submitted in draft form. The report was never finalized.

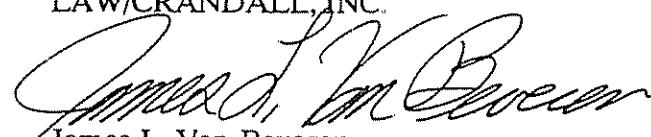

The configuration of the marina has changed somewhat from that described in our April 4, 1988 report. Currently, the marina is planned to extend closer to Ballona Creek and two islands are planned inside the marina. The entrance channel will also be located further to the south. The marina is still planned to be developed by excavating to about Elevation -15. The other aspects of the marina, including perimeter treatment and surrounding development are unchanged from that described in the report.

August 6, 1991
(L91096.AFB)

Our report of April 4, 1988 may still be used for preliminary design purposes. As discussed in that report, prior to final design, the recommendations should be reviewed to determine the appropriateness of the design data based on the final configuration.

Sincerely,

LAW/CRANDALL, INC.

James L. Van Beveren
Vice President
Director of Engineering Services

1.0 SCOPE

This report presents the results of a preliminary geotechnical investigation of the site of a proposed marina to be located within Parcel A of the Playa Vista Development. The locations of the site and our exploration borings are shown on Plate 1, Site Plan. We previously performed a preliminary environmental audit for the project, and presented the results in our report dated December 21, 1988 (our Job No. F-88473). We performed a concurrent study to determine the location of an existing natural gas storage reservoir, and the effect of the reservoir on the marina construction. The results of that study were presented in a report dated March 31, 1989 (LCA L89101.AEB).

This investigation was authorized to determine the static physical characteristics of the soils beneath the site and to provide recommendations for: perimeter wall design including recommended lateral pressures and foundation support; various sloping configurations of perimeter treatment; information on excavation and dewatering; and preliminary information for location of building foundations adjacent to the perimeter. The investigation was to include a geologic-seismic hazards study to determine any geologic hazards that might affect the proposed construction.

This investigation is based on the presently anticipated layout of the marina. Prior to final design, the recommendations contained herein should be reviewed to determine the appropriateness of the design data based on the final configuration. Additional explorations may be required.

The recommendations contained herein are based on the results of our field explorations and laboratory tests, the engineering analyses based thereon, and on the geologic studies. The results of the exploration

borings and laboratory tests are presented in the attached Appendix A. Cone penetration test results are presented in Appendix B.

Our professional services have been performed using that degree of care and skill ordinarily exercised, under similar circumstances, by reputable geotechnical consultants practicing in this or similar localities. No other warranty, expressed or implied, is made as to the professional advice included in this report. This report has been prepared for Howard Hughes Properties and their design consultants to be used solely in the preliminary design of the proposed marina. The report has not been prepared for use by other parties, and may not contain sufficient information for purposes of other parties or other uses.

2.0 PROPOSED CONSTRUCTION

It is proposed to construct a marina within the subject 139-acre Parcel A; the marina will connect with the existing Marina del Rey. The configuration of proposed marina, as presently planned, is shown on Plate 1. The configuration shown is based on the Playa Vista Land Use Plan; we understand that other configurations are being studied. The marina will be developed by excavating and dredging to about Elevation -15, some 23 to 33 feet below the existing grade. The perimeter treatment for the marina may consist of gravity retaining walls, sheet pile walls, slopes, or combinations of walls and slopes.

The areas surrounding the marina are to be developed with hotels, office buildings, retail stores, and condominiums. Some of these structures may be built near or adjacent to the marina perimeter. Foundation design data for these structures are not within the scope of this report.

3.0 SITE CONDITIONS

The site is located northwest of Lincoln and Culver Boulevards in the Marina del Rey district of Los Angeles County. The property is bordered on the north and northwest by Fiji Way and on the southeast by the Ballona Creek Channel. There are seven wells on or adjacent to the site. The wells were originally drilled as oil wells. One of the wells has been abandoned. The other six wells are operated by the Southern California Gas Company in conjunction with their subterranean natural gas storage reservoir for gas withdrawal and monitoring. There are pipelines between the wells.

The site has been previously filled with excavated materials and dredgings from the existing marina and Ballona Creek Channel, and is about 8 to 18 feet above sea level.

Except for the wells, the property is currently vacant; various dirt roads and paths cross the site. There were structures formerly on the site including radio towers; the foundations may still be in place. The eastern portion of the site was formerly used as a dump for celery trimmings. The site is fenced to restrict access.

The Ballona Creek Channel was excavated in the 1930s and the excavated/dredged soils were placed on the southern portion of the site. Material dredged for development of the existing Marina del Rey in the early 1960s was deposited on the site as hydraulically placed fill.

4.0 GEOLOGY

4.1 GENERAL

The project site is located on the Los Angeles Coastal Plain within the Peninsular Ranges geomorphic province of California which extends from Baja California on the south to the Transverse Ranges on the north. The Peninsular Ranges geomorphic province is characterized by northwest-southeast trending mountain ranges and basins composed predominantly of Mesozoic era igneous and metamorphic rocks and Cenozoic era sedimentary rocks.

The site is situated in the Ballona Creek Flood Plain at the north end of the El Segundo Sand Hills. The Ballona Escarpment, which is an erosional feature caused by the ancient Los Angeles River that flowed through Ballona Gap, is located about one-half mile to the south of the site. The Ballona Escarpment rises approximately 120 to 140 feet above the flood plain and is composed of Pleistocene sediments, dune sand deposits, and the underlying Lakewood and San Pedro Formations.

The site is located approximately 2½ miles west-southwest of the Baldwin Hills, which are part of a northwest trending succession of hills which represent the surface expression of the Newport-Inglewood Fault Zone.

The Pacific Ocean is located approximately one-half mile west-southwest of the site. The current site elevation is about 8 to 18 feet above mean sea level (U.S. Geological Survey datum - Mean Sea Level = Elevation 0).

The southwestern portion of the site overlies a section of the Del Rey Hills area of the Playa del Rey Oil field.

The geology and topography in the vicinity of the site are shown on Plate 2, Local Geology. A section showing the typical soil profile beneath the site is presented on Plate 3, Generalized Soil Profile.

4.2 GEOLOGIC MATERIALS

4.2.1 Fill

Fill soils, 9 to 17½ feet in thickness, were encountered in the borings. The fill consists of silt, clay, and silty sand. The silt and clay are soft to medium stiff; the silty sand is loose to medium dense. There are traces of organic matter in the clayey soils. Debris was encountered and the presence of a hydrocarbon was detected in the fill in Boring 17. The majority of the fill was apparently placed hydraulically during dredging of the Marina del Rey harbor although some dump fill is also apparent. The fill appears to have been placed directly over vegetation present on the surface of the natural soils.

4.2.2 Holocene Deposits

Beneath the fill, the site is underlain by Holocene alluvium extending to an estimated depth of 100 feet below ground surface (California Department of Water Resources, 1961). The alluvial deposits appear to be fairly uniform throughout the parcel, consisting predominantly of cohesive soils to depths of about 50 to 70 feet underlain by dense sand and gravel. The upper cohesive soils

consist of soft to medium stiff silts with some layers of loose to dense silty sand and sand with occasional minor layers of peat. The alluvial deposits are of estuarine origin and contain decomposing organic materials which generate the organic odor (hydrogen sulfide) noted on the boring logs.

The dense sand and gravel deposits were encountered at depths between 48 and 67 feet. These coarser sediments were described by Poland (1959) as the "50-foot gravel," a ground water aquifer.

4.2.3 Pleistocene and Older Deposits

Early Pleistocene age San Pedro Formation sediments underlie the Holocene deposits. These sediments consist primarily of sand with some gravel. Locally, there are thick interbeds of silt. The San Pedro Formation deposits extend to an estimated depth of 200 feet below the site (Poland, 1959). In our other recent investigations in the Ballona Gap area that penetrated into the San Pedro Formation, the sediments consisted of silts and clays.

At depth, approximately 5,800 feet of Tertiary age sedimentary rocks underlie the San Pedro Formation. These sedimentary rocks rest upon metamorphic basement rocks of the Mesozoic (?) age Catalina Schist.

4.3 GROUND WATER

The site is within the Santa Monica Hydrologic Subarea of the Coastal Plain of Los Angeles. Regional ground water levels are near sea level. Ground water was encountered in our borings at

depths of about 7 to 15½ feet below ground surface corresponding to elevations of about 3 feet below sea level to 7 feet above sea level.

Nearly all ground water from the Ballona Gap subunit, which underlies the project area, has been degraded. This degradation has been attributed to sea water intrusion resulting from overpumping in the past.

4.4 OIL AND GAS WELLS

One oil well, designated Del Rey #16, is located in the planned area of excavation. Records on file for the well indicate that it was abandoned on April 17, 1938, in accordance with D.O.G. requirements in effect at that time. The abandonment report (dated May 3, 1938) indicates that the well was abandoned by plugging with cement at depths of 5,981 to 6,074 feet, 1,450 to 1,700 feet, and 502 to 732 feet. This well may have to be reabandoned following current D.O.G. requirements to allow the completion of the proposed marina.

Oil wells Del Rey #13, #14, #15, #17, #18, and #19 are currently used as monitoring and withdrawal wells for gas storage in the Playa del Rey Oil Field, see Plate 1 for the locations of the wells.

4.5 NATURAL GAS STORAGE

The Southern California Gas Company owns the existing on-site and adjacent wells, Del Rey #13 through #19, and uses the underlying Playa Del Rey Oil field for storage of natural gas. Gas storage is

generally at a depth of approximately 6,200 feet below the surface (D.O.G., 1974), although an easement allows storage at depths of 500 to 7,00 feet below ground surface. The lateral extent of the Playa Del Rey Oil Field is shown on Plate 2.

4.6 GEOLOGIC HAZARDS

4.6.1 General

The geologic hazards at the site are essentially limited to those caused by earthquakes. The major cause of damage from earthquakes results from violent shaking from earthquake waves; damage to structures from surface rupture is typically confined to facilities located directly over a fault, and therefore is much less frequent. Violent earthquake shaking would occur not only immediately adjacent to the earthquake epicenter, but within many miles in all directions.

4.6.2 Faults

The numerous faults in Southern California include active, potentially active, and inactive faults. Based on criteria modified from the Association of Engineering Geologists (1973), a fault is considered active if it has moved during historic time (approximately the last 200 years), or is included in a State of California Special Studies Zone for fault rupture hazard. A potentially active faults has moved in the last two million years, but not during historic time. Faults which have not moved in the last two million years are considered inactive.

The closest active fault to the site is the Inglewood Fault of the Newport-Inglewood Fault Zone, located 4.4 miles to the east-northeast. The large number of low magnitude earthquake epicenters on or near the Newport-Inglewood Fault indicates that it is active, at least at depth. The 1933 Long Beach earthquake (Magnitude 6.3) occurred on the Newport-Inglewood Fault Zone.

The active Malibu Coast Fault is located about 7 miles northwest of the site. The major San Andreas Fault Zone is located about 43 miles north-northeast of the site.

The potentially active Charnock Fault is mapped as being located 1.7 miles east-northeast of the site. This fault trends north-northwesterly from the Gardena area, beneath the El Segundo Hills, across Ballona Creek, and through the alluvial narrows southwest of Beverly Hills. We performed a detailed investigation to locate the Charnock Fault in the area of Parcel D between Jefferson Boulevard and the Ballona Escarpment. The results were presented in our report dated May 25, 1988 (LCA AE-86125-L). During our investigation, evidence of the fault was not encountered in late Pleistocene age materials nor was there evidence of a fault-related ground water barrier within the 47- to 71-foot depth explored by our borings.

Other nearby potentially active faults include the Overland Fault located 2½ miles east-northeast of the site, the Santa Monica-Hollywood Fault, 5 miles to the north, and the Palos Verdes Fault, 5 miles to the south-southwest.

The California Division of Oil and Gas report on the Playa del Rey Oil Field (1974) indicates one inactive fault underlying and six small inactive faults near the project area. These faults are depicted as offsetting Miocene age bedrock, but not offsetting Pliocene age rock. This indicates that the faults have been inactive since the beginning of Pliocene (5 million years) time. The potential for surface rupture from these inactive faults is extremely low.

4.6.3 Seismicity

In the last 60 years, three earthquakes have caused major damage in the metropolitan Los Angeles area. These events are the Long Beach, San Fernando, and Whittier Narrows earthquakes. The Long Beach earthquake occurred March 10, 1933. The epicenter of this event was located about 35 miles southeast of the site. This earthquake, although only Richter Magnitude 6.3, ranks as one of the major disasters in Southern California. The majority of damage occurred in structures which are now considered to have been of substandard construction and/or were located on filled or saturated ground.

The epicenter of the Magnitude 6.5 February 9, 1971 San Fernando earthquake was located about 29 miles north of the site. Surface rupture occurred on various strands of the San Fernando Fault Zone including the Sylmar and Tujunga Faults. The large amount of damage caused by this earthquake led to the adoption of more stringent building codes.

The Magnitude 5.9 Whittier Narrows earthquake occurred October 1, 1987 on a previously unrecognized east-west trending reverse fault. The earthquake epicenter was located approximately 22 miles east-northeast of the proposed marina. The majority of structural damage resulting from the earthquake occurred in buildings constructed prior to the more stringent building codes which were developed after the 1971 San Fernando Earthquake.

More recently, two Magnitude 5.0 earthquakes, occurring on December 3, 1988 and January 18, 1989, have shaken the greater Los Angeles area. These earthquakes were not associated with a great amount of damage. The epicenter of the December 3rd earthquake was in the Pasadena area (verbal communication, California Institute of Technology) about 21 miles to the northeast of the site. The January 18, 1989 earthquake occurred offshore in the Santa Monica Bay (verbal communication, California Institute of Technology); the epicenter was located about 9 miles west-southwest of the site.

4.6.4 Liquefaction and Seismically Induced Settlement

Liquefaction potential has been found to be the greatest where the ground water level is shallow and loose fine sands occur within a depth of about 50 feet or less. Liquefaction potential decreases with increasing grain size and clay and gravel content, but increases as the ground acceleration and duration of shaking increase. The County of Los Angeles Seismic Safety Element indicates that the project site is located in an area subject to potential liquefaction based on shallow ground water.

The natural soils consist of soft to medium stiff deposits of silt to depths of 50 to 70 feet with layers of loose to dense silty sand and sand underlain by dense sand and gravel. The relative density of the silty sands and sands within the upper 50 to 70 feet varies from about 60% to 80%. The layers of silty sand and sand within the upper 50 to 70 feet are typically less than three feet in thickness (although an eight-foot thick layer was encountered in one boring) and are confined within layers of cohesive silts. The layers of the looser silty sand and sand have a total thickness of up to 18 feet at some of our boring locations. The relative density of the sand and gravel below the 50- to 70-foot depth is greater than 80%.

Water was measured in our borings at depths of 7 to 15½ feet, corresponding to an elevation of 3 feet below sea level to 7 feet above sea level.

In the event of a severe earthquake on the San Andreas Fault Zone or a moderate earthquake on one of the nearby capable faults, liquefaction of the looser sand and silty sand deposits in the upper 50 feet could occur. The liquefaction would not be extensive across the site, but would be confined to the looser sandy layers of limited thickness. Because the potentially liquefiable soils are confined within cohesive layers, sand boils are not expected to develop. Settlements ranging from about one to four inches should be anticipated due to liquefaction.

4.6.5 Stability

For the most part, the site is essentially level with no known slope stability problems. Slopes present on-site are limited to minor 2:1 (horizontal to vertical) graded (both cut and fill) slopes along the existing channel in the northeastern portion of the site, adjacent to Culver Boulevard, along service roads for the existing oil and gas wells, and bordering the Ballona Creek Channel. These graded slopes are generally ten feet or less in height with no indications of major slope instabilities.

The potential for slope stability problems on-site is judged to be low. Additionally, the site is not on or in the path of any existing or potential landslides.

4.6.6 Subsidence

The site is underlain by the Playa del Rey Oil Field which has been identified as a subsidence area in the Urban Geology Master Plan (California Division of Mines and Geology, 1973). Development within the field began in the 1920s with peak production in the area underlying the site in 1935 (California Division of Oil and Gas, 1974). Minor subsidence on the order of 0.02 to 0.07 feet per year was noted between the years 1925 and 1938 (Castle and Yerkes, 1976) within the vicinity of the oil field. These rates of subsidence apparently decreased with no subsidence noted in the area between 1949 and 1955 (Castle and Yerkes, 1976). The field has been essentially depleted and is now used for underground natural gas storage by the Southern California Gas Company. Accordingly, the potential for continued subsidence at the site is low.

4.6.7 Peat

Peat deposits have been known to cause subsidence due to oxidation and shrinkage in the event of drying. As stated previously, layers of peat were encountered in our borings. The peat layers are below the ground water level and not subject to oxidation or drying. Accordingly, the potential for subsidence due to peat oxidation or drying is low.

4.6.8 Collapsible Soils

Collapsible soils are those soils that are subject to increased consolidation with increase in moisture content. The majority of the soils at the site are either below water level or have been subjected to higher water levels in the past. Collapsible soils were not encountered within our investigation.

4.6.9 Tsunamis and Seiches

Ocean access for the proposed marina will be through the existing entrance channel for Marina del Rey. The estimated run-up for the 100-year tsunamis (seismic sea wave) at the mouth of the entrance channel is 7.9 feet (Houston and Garcia, 1974). Tsunamis could cause the water level in the proposed marina to rise accordingly. Locally generated tsunamis have the potential for greater run-up, although there have been no historic tsunamis generated from local offshore earthquakes.

Seiches are oscillations in a body of water caused by earthquake shaking. The resultant "sloshing" of a captive body of water may

occur during moderate to great earthquakes of Richter Magnitude 5.0 and greater. The result of seiching of the planned marina could cause the water level to temporarily rise or fall a few inches to a few feet.

4.6.10 Flooding

The subject property is located within "Zone C" as designated by Federal Emergency Management Agency for flood hazard (1985). "Zone C" designates areas of minimal flooding outside the 100-year and 500-year flood zones. Ballona Creek which lies along the south-eastern boundary of the subject parcel has been channelized to contain the 100-year flood zone. To the north and west of the site, existing improvements along the main channel and the harbor basins contain the 100-year flood zone within Marina del Rey. Estimated base flood elevations within the Marina del Rey facilities are six feet. Similar base flood elevations may be expected within the proposed marina.

5.0 CONCLUSIONS AND RECOMMENDATIONS

5.1 GENERAL

Based on the geologic findings, no active or potentially active faults are known to exist within the site. Accordingly, no surface rupture hazard is deemed to affect the site. The inactive fault beneath the site will not impact the development. The site could be subject to strong ground motion in the event of an earthquake. Due to the nature of the project, hazards due to tsunamis and seiches are inherent. The 100-year run-up in the project area due to tsunamis is 7.9 feet. The potential 100-year flood elevation is approximately six feet, similar to that designated for the existing Marina del Rey facilities. The effects of ground shaking, tsunamis, seiches, and flooding can be mitigated if structures are designed and constructed with current building codes and proper engineering practice. Construction of the marina is not expected to affect the natural gas storage reservoir nor is the reservoir expected to have any effect on the marina.

The proposed marina may be developed as planned. The perimeter treatment may consist of vertical walls, revetted slopes, or combinations of slopes and walls. The upper soils are relatively weak and the required slopes will need to be relatively flat.

The upper soils are not suitable for direct support of retaining walls or other structures on spread footings. Driven piling will be required for support on major walls or other structures. Low walls could be supported on spread footings if the soils beneath the footings are excavated and replaced as compacted fill.

Liquefaction is expected to occur in localized zones of loose silty sand. Based on the borings and cone penetration tests, most of the layers of loose silty sand and sand are less than three feet in thickness. In the event of liquefaction, localized settlement of the ground surface of about one to four inches could occur; the settlement is not expected to be uniform. However, the liquefaction is not expected to affect the stability of the proposed perimeter walls, because of its localized nature. Localized slope sloughing could, however, occur. We do not believe that it will be necessary to design the facilities to resist any liquefaction effects; these conclusions should be verified prior to final design after the design scheme is finalized.

Water was measured in our borings at depths of 7 to 15½ feet. The upper fill soils may be excavated to near the water level using conventional equipment. Below these depths, the soils are not expected to be capable of supporting conventional equipment. Draglines or large backhoes operating from levels above water level could be used to excavate below water level. Dredging could also be considered. Dewatering could be performed to facilitate excavation. The soils are relatively impermeable and trapped water pockets may be encountered during excavation even if the site is dewatered.

The conclusions and recommendations presented below are preliminary and necessarily general in nature. The data contained in this report should be reviewed prior to preparing final plans for the site development. The data are not intended for final design of buildings adjacent to the marina.

5.2 FOUNDATIONS

5.2.1 General

The proposed gravity retaining walls should be supported on driven friction piling. The piles should be driven through the soft upper soils and develop their support into the dense sand and gravel which occur about 60 feet below existing grade (30 feet below dredged level). Minor retaining walls may be supported on spread footings.

5.2.2 Driven Piling

5.2.2.1 Driven Pile Capacities

The downward and upward capacities of 14-inch-square prestressed concrete piles are presented on Plate 4, Driven Pile Capacities. Dead plus live load capacities are shown. A one-third increase may be used when considering wind, seismic, or berthing loads. The indicated capacities are based on the supporting characteristics of the soils and would be applicable for either foundation piling or slip guide piling. The pile section itself should be checked to verify its capability of supporting the imposed loads.

The capacities are presented as a function of penetration into the dense sand and gravel, for various depths to the sand and gravel. The piles should be driven at least five feet into the dense sand and gravel, which was encountered below Elevation -38 to -55; the elevation of the surface of the dense sand and gravel at each boring location is shown on Plate 1.

Piles in groups, if any, should be spaced at least three feet on centers. If so spaced, no reduction in the downward capacity of the piles due to group action need be considered in design.

The settlement of the walls, supported on driven piling in the manner recommended, will be depend on the loads imposed but should be well within acceptable limits.

5.2.2.2 Lateral Resistance

The soils adjacent to an 14-inch-square concrete pile may be assumed to resist horizontal thrusts applied at the top of a pile. The available lateral resistance is presented in the following table.

	<u>1/4-inch Deflection (pounds)</u>	<u>1/2-inch Deflection (pounds)</u>
Free Head	3,500	7,000
Fixed Head	10,000	20,000

The lateral resistance of other sizes of piles would be proportional to the width. The presented capacities are for total loads, including wind, seismic, and impact loads.

In calculating the maximum bending moment in a pile, due to the lateral load applied at the top of the pile, the lateral load may be multiplied by an assumed moment arm of four feet. For design, it may be assumed that the maximum bending moment will occur at the pile cap or at the adjacent grade, whichever is lower, and that the

bending moment will decrease to zero at a depth of 20 feet below the bottom of the pile cap or adjacent grade.

Batter piles may also be used to resist lateral loads. Batter piles should also be driven at least five feet into the dense sand and gravel. The axial capacity of a batter pile may be taken as equal to the capacity of a vertical pile driven to the same tip elevation.

5.2.2.3 Installation

We anticipate that the driving resistance will range from very low to high. All piles should be driven to the lengths discussed above, except as may be modified on the basis of the driving criteria defined on Plate 5, Pile Driving Criteria. The piles may run until they encounter a stiffer or denser layer. The driving resistance may be moderately high in the silty sand and sand layers and in the stiffer silt layers. Hard driving may be encountered within the deeper dense sand and gravel, and some predrilling may be required. The diameter of the predrilled hole should not exceed the width of the pile. Predrilling may be performed to within five feet of the design tip elevation of the pile.

Prior to ordering the production piles, an indicator pile program will be required to evaluate the driving resistance prior to ordering production piling. The program can be developed after the design is finalized.

5.2.3 Spread Foundations

5.2.3.1 Bearing Value

Retaining walls less than about six feet in height and extending less than ten feet below the existing ground surface, may be supported on spread footings established in properly compacted fill. Footings extending at least 2 feet below the adjacent grade and underlain by at least three feet of compacted fill may be designed for a soil bearing pressure 1,500 pounds per square foot. The allowable bearing pressure would have to be reduced if the footings are located near the face of a downward slope.

While the actual bearing value of any required fill will depend on the material used and the compaction methods employed, the quoted bearing values will be applicable if acceptable soils are used and are compacted as recommended. The bearing value of the fill should be confirmed during the grading.

5.2.3.2 Lateral Resistance

A coefficient of friction of 0.4 may be used between the footings and the supporting soils. The passive pressure against footings may be assumed to be equal to that developed by a fluid with a density of 250 pounds per cubic foot. The available passive pressure would have to be reduced if the footings are near the face of a downward slope.

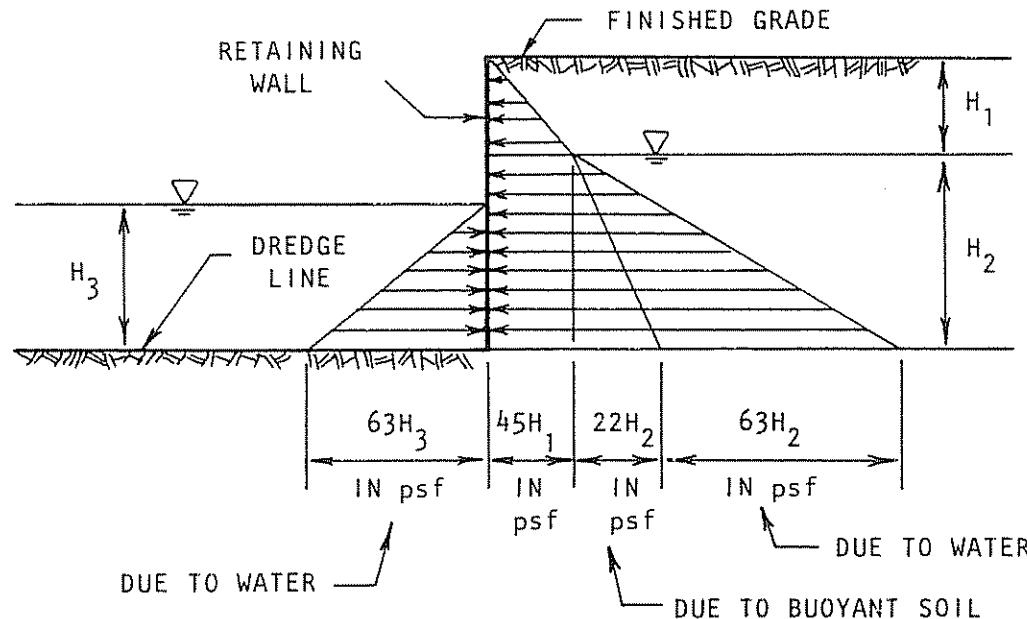

5.2.3.3 Foundation Observation

To verify the presence of satisfactory soils at design elevations, all footing excavations should be observed by personnel of our firm. Inspection of footing excavations may also be required by the appropriate reviewing governmental agencies. The contractor should familiarize himself with the inspection requirements of the reviewing agencies.

5.3 WALLS BELOW GRADE

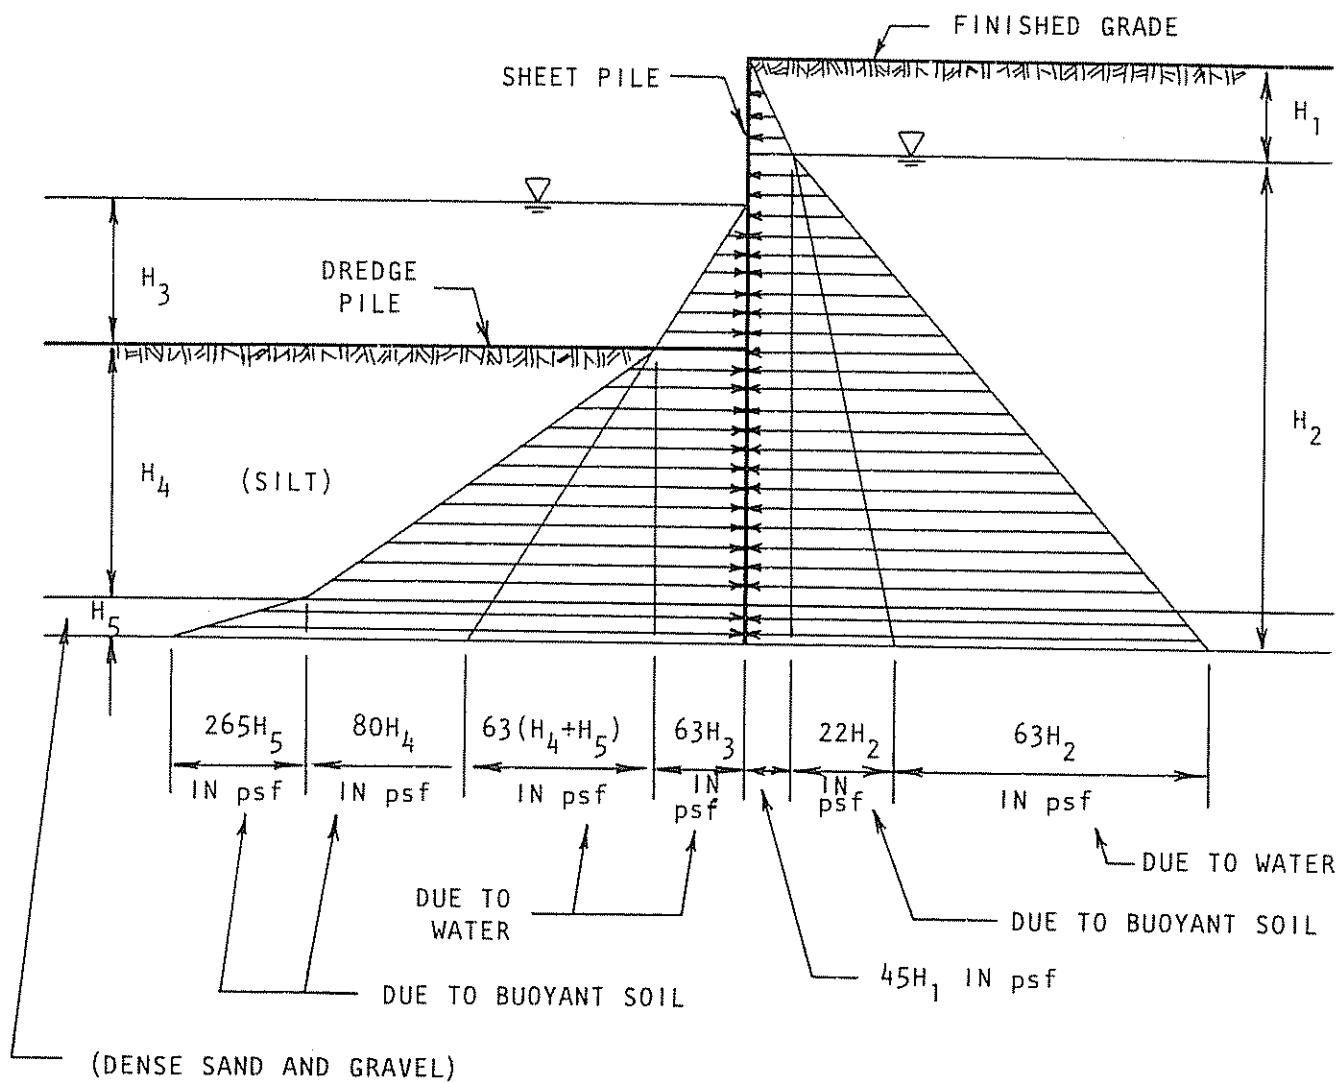

5.3.1 Gravity Retaining Walls

For design of gravity retaining walls, it may be assumed that the lateral pressure of the on-site soils with level backfill above the water level will be equal to that developed by a fluid with a density of 45 pounds per cubic foot. Below the water level, the lateral pressure due to the soil and the water will be equal to that developed by a fluid with a density of 85 pounds per cubic foot. (The soil buoyant pressure would be 22 pounds per cubic foot and the water would be 63 pounds per cubic foot.) The recommended pressure distribution is shown on the following page. (The water pressure on the marina side of the wall may be considered in the design.) If sloping backfill is used, the pressure would be greater; we can provide the necessary data when the configuration is known.

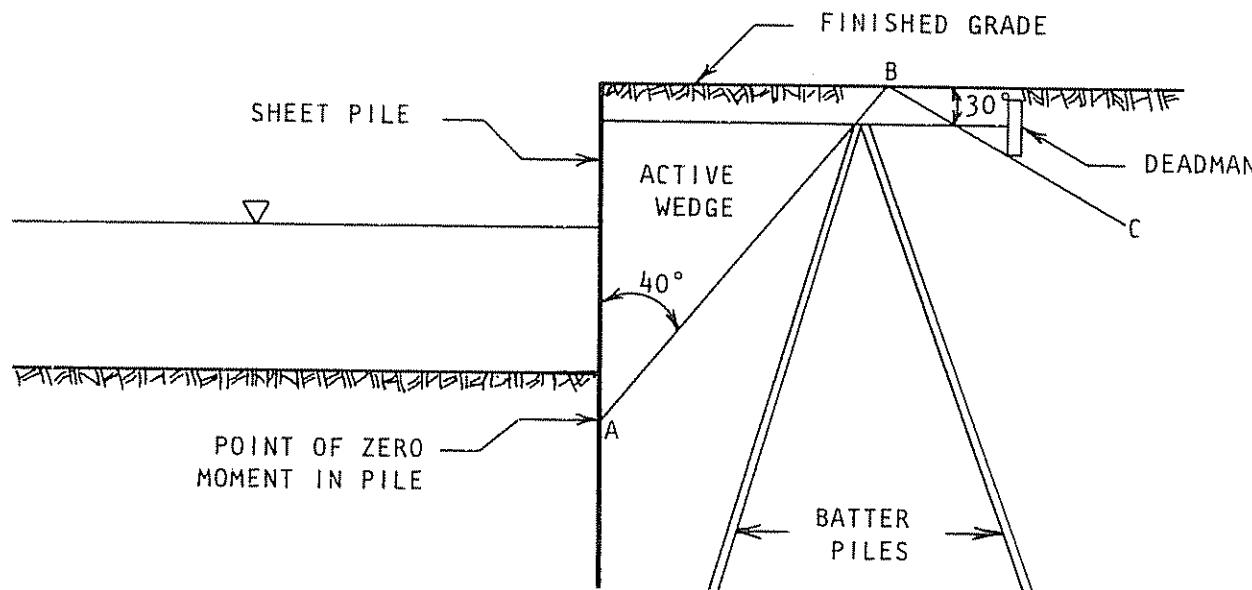

5.3.2 Sheet Pile Walls

The sheet pile walls with level backfill should be designed to resist the lateral pressures imposed by the soils and the ground water as shown on the following page. Sheet piles should extend at least two feet into the dense sand and gravel (see Plate 1 for elevations of dense sand and gravel at the locations explored.) If sloping backfill is used, the pressures would be greater; we can provide the necessary data when the configuration is known.

It may be desired to restrain the upper portion of the sheeting by using tie-rods. The tie-rods should connect to either deadmen or batter piles. The locations of the anchor deadmen or batter piles are illustrated below. The passive resistance of the deadmen may be assumed to be equal to that developed by a fluid with a density of 250 pounds per cubic foot. A coefficient of friction of 0.4 may be used between the deadman and the supporting soils. Lines A-B

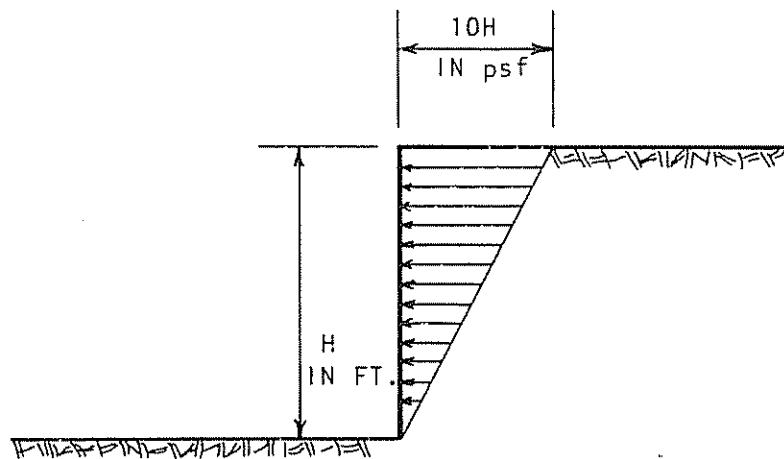

and B-C define the limits of the active and passive wedges, respectively. The entire deadman should be to the right of line B-C. Where a tie-rod is connected to piles, the connection should be to the right of line A-B.

5.3.3 Seismically-Induced Earth Pressure

It is our opinion that the incremental increase in earth pressure due to seismic loading on the walls of the structures will be low and will merely result in a reduction in the factor of safety. If it is desired to maintain the same factor of safety during an

earthquake as under static conditions, we suggest the use of the following seismically induced earth pressure distribution. This pressure distribution would be in addition to the earth pressure and any surcharge.

5.3.4 Backfill

All required backfill for walls below grade should be mechanically compacted in layers not more than eight inches in thickness to at least 90% of the maximum density obtainable by the ASTM Designation D1557-70 method of compaction. Proper compaction of the backfill will be necessary to reduce settlement of the backfill and consequent settlement of overlying slabs and paving. In order to minimize the potential for development of differential hydrostatic pressures on the walls, the backfill should consist of granular, free-draining soils. It may be possible to use the on-site silty sand soils; the silt soils should not be used.

Even at 90% compaction, some settlement may occur within the backfill. Accordingly, provisions should be made for some possible settlement of overlying slabs and paving. Also, we suggest that any utility lines partially supported on the backfill and crossing the walls be designed to accept differential settlement, particularly at the points of entry through the walls.

5.4 GRADING

5.4.1 Excavation

5.4.1.1 Cut Slopes

The allowable permanent slope inclination will vary with the height of the slope. The allowable slope inclinations for various slope heights are presented in the following table:

Slope Height <u>(feet)</u>	Slope Inclination <u>(Horizontal to Vertical)</u>
0 to 10	2:1
10 to 20	3:1
20 to 30	4:1

We recommend that combinations of slopes with gravity retaining walls above not be used. It would be possible to use a slope at the toe of a sheet pile wall. We can provide data for design of sheet pile walls with slopes when the desired configuration is known. The slopes should be revetted to protect against erosion

from tide fluctuations, tidal currents, wave action, prop wash, etc. The revetment should be placed as soon as possible after the slopes are excavated.

5.4.1.2 Dredging

As discussed, dredging excavation methods may be needed below water level. This could involve the soils between depths of about 10 and 30 feet. Based on our borings, the soils in this zone are primarily silts. Although the materials are slightly cohesive we believe that they could be excavated using dredging techniques. However, because of their fine-grained nature, sedimentation of these materials will be slow, and drainage of the dredged materials will require relatively long periods of time.

5.4.1.3 Dewatering

Depending on the final design and selected construction methods for the marina perimeter, dewatering of the site will be required. Well points and/or deep wells could be used to achieve proper dewatering. The lowering of the water table will cause compression of the underlying material. Our analyses indicate that $\frac{1}{2}$ o $\frac{1}{2}$ inch of surface subsidence will occur for each foot the ground water surface is lowered. If the ground water is lowered 15 feet, this will result in about 6 inches of subsidence. Our calculations assume that the site has not been previously dewatered. If the site has been previously dewatered, the anticipated settlement would be less.

The extent of the ground water drawdown away from the excavations will vary depending on the method of dewatering used.

If the site is to be dewatered, supplementary studies to determine the required pump rates and anticipated drawdown should be performed.

5.4.2 Compacted Fill

5.4.2.1 General

The site is underlain by existing hydraulic fill, and some dumped fill. This material is not suitable for foundation support. Retaining walls less than about six feet in height could be supported on spread footings in compacted fill if the existing fill soils to depths of three feet below the footings are excavated and replaced as a compacted fill.

Elsewhere, excavation of the upper soils to a depth of about two feet below the existing grade will be required prior to placing any new fill. After making that excavation, the exposed soils should be carefully observed by competent geotechnical personnel to verify removal of unsuitable material. As discussed, a former dump, referred to as the celery dump, existed on the east portion of the site. The feature was not encountered in the borings. If encountered during grading, special handling of these materials may be necessary.

5.4.2.2 Site Preparation

Where spread footings will be used, the on-site soils should be excavated to a depth at least three feet below footing bottoms and five feet beyond the footings in plan. Elsewhere, where new compacted fill is to be placed, the soils should be excavated to at least two feet below existing grade. Next, the exposed soils should be scarified to a depth of six inches and rolled with heavy compaction equipment. The upper six inches of exposed soils should be compacted to at least 90% of the maximum density obtainable by the ASTM D1557-70 method of compaction. The exposed soils may be wet and soft. In this event, the soils should not be scarified, instead a geotextile and a layer of gravel should be placed to provide a stable working surface for men and equipment.

5.4.2.3 Compaction

After compacting the exposed soils or placing the layer of gravel, the required fill should be placed in loose lifts not more than eight inches in thickness and compacted to at least 90%. It is recommended that the soils be compacted at a moisture content varying no more than 2% below or above optimum moisture content.

5.4.2.4 Material For Fill

The on-site silty sand and sandy silt soils, less any debris or organic matter, may be used in the required fills beneath footings. The on-site clayey silt soils should not be used. Any required imported fill should consist of relatively non-expansive soils.

The Expansion Index of the select soil should be less than 35. The imported material should contain sufficient fines (binder material) so as to result in a stable subgrade.

5.4.2.5 Geotechnical Observation

The excavation of the upper soils and the compaction of all required fill should be observed and tested by our firm. Any imported fill material should be approved for use prior to importing.

5.4.2.6 Subsidence

The settlement due to the placement of the existing fill at the site is complete. If additional fill is placed on the site during development of the marina, there will be additional settlement of the areas receiving fill. We estimate that the areal settlement due to the placement of additional fill will be up to about two inches per foot of fill placed. We estimate that 80% of this settlement will occur within about one year after completion of this fill. The rate of settlement can be effectively increased by placing a surcharge fill. We can develop surcharge criteria if necessary.

5.5 FOUNDATIONS FOR STRUCTURES ADJACENT TO MARINA PERIMETER

It is anticipated that structures may be constructed adjacent to the perimeter of the marina in the future. Major structures adjacent to the perimeter of the marina should be supported on piling.

DOWNWARD PILE CAPACITY in Kips

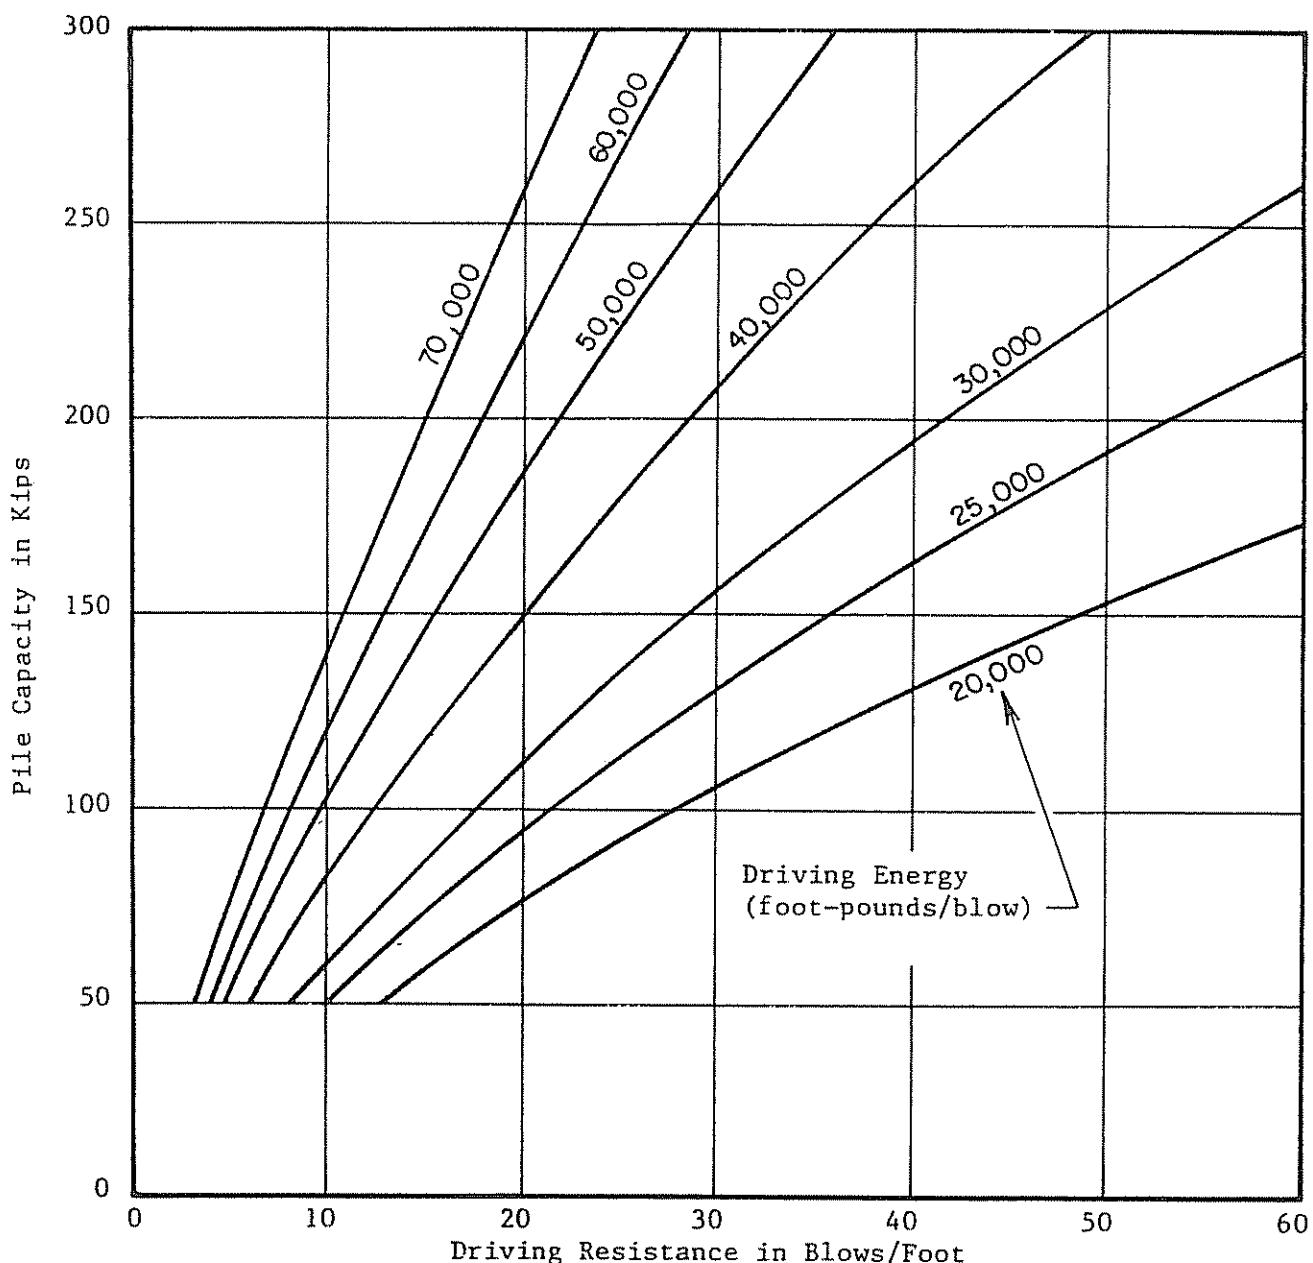

UPWARD PILE CAPACITY in Kips

NOTES :

- (1) The indicated values refer to the total of dead plus live loads; a one-third increase may be used when considering wind or seismic loads.
- (2) Piles in groups should be spaced a minimum of 3 feet on centers.
- (3) The indicated values are based on the strength of the soils; the actual pile capacities may be limited to lesser values by the strength of the piles.

DRIVEN PILE CAPACITIES

NOTES:

- 1) The above driving resistance should be obtained for the last foot of driving at design pile length. If the driving resistance at the design length is less than above, the piles should be lengthened until the desired driving resistance is obtained.
- 2) As an alternate to lengthening when low driving resistance is obtained, the piles may be allowed to set overnight and the number of blows to drive the pile one inch the following day should be determined. If the restarting resistance is at least two times the above criteria, the pile may be considered satisfactory.
- 3) If driving resistance of three times the above criteria is encountered within five feet of design length, the pile driving may be stopped.

PILE DRIVING CRITERIA

LeROY CRANDALL AND ASSOCIATES

APPENDIX A
EXPLORATIONS

The soil conditions beneath the site were explored by drilling 20 borings at the locations shown on Plate 1. Five cone penetration tests were performed to supplement the exploration borings. The cone penetration test results are presented in Appendix B.

Borings 1 through 7, 11, 14, and 16 through 20 were drilled to depths of about 60 feet below the existing grade using 5-inch-diameter rotary wash-type drilling equipment with drilling mud to prevent caving. The mud was removed from some of the borings following completion of the drilling to permit measurement of the water level. Borings 8, 9, 19, 12, 13, and 15 were drilled to depths of between 16 and 20 feet below the existing grade using 16- and 18-inch bucket-type drilling equipment. Bucket-type borings were also drilled to depths of between 11½ and 16 feet below the existing grade adjacent to Borings 1, 6, 16, and 18 to provide information on the water levels. Drilling mud or casing was not used to extend the bucket borings to the depths drilled. Caving and squeezing in of the boring walls occurred during drilling as noted on the boring logs.

The soils encountered were logged by our field technician, and undisturbed and loose samples were obtained for laboratory inspection and testing. The logs of the borings are presented on Plates A-1.1 through A-1.20; the depths at which undisturbed samples were obtained are indicated to the left of the boring logs. The energy required to drive the sampler twelve inches is indicated on the logs. Standard penetration tests were performed in selected borings; the results are indicated on the boring logs. The soils are classified in accordance with the Unified Soil Classification System described on Plate A-2.

LABORATORY TESTS

The field moisture content and dry density of the soils encountered were determined by performing tests on the undisturbed samples. The results of the tests are shown to the left of the boring logs.

The liquid limit and plasticity index of selected samples were determined. In order to assess whether or not the soils were organic, the liquid limit test was repeated on some of the samples after they were oven dried. The results of the tests are presented on the boring logs.

Direct shear tests were performed on selected undisturbed samples to determine the strength of the soils. The tests were performed at field and increased moisture contents and at various different surcharge pressures. Tests were also performed on remolded samples compacted to 90%. The yield-point values determined from the direct shear tests are presented on Plates A-3.1 and A-3.2, Direct Shear Test Data.

Confined consolidation tests were performed on 23 undisturbed samples to determine the compressibility of the soils. The samples were tested at field moisture content. The results of the tests are presented on Plates A-4.1 through A-4.12, Consolidation Test Data.

To determine the particle size distribution of the soils and to aid in classification, mechanical and hydrometer analyses were performed on six samples. The results of the analyses are presented on Plates A-5.1 through A-5.3, Particle Size Distribution.

The optimum moisture content and maximum dry density of the soils were determined by performing compaction tests on samples from Borings 8 and 9. The tests were performed in accordance with the ASTM Designation

D1557-70 method of compaction. The results of the tests are presented on Plate A-6, Compaction Test Data.

Permeability tests were performed on ten undisturbed samples to determine the coefficient of permeability of the soils. The samples were tested under confining pressures of between 200 and 1,000 pounds per square foot. The test results are presented on Plate A-7, Permeability Test Data.

Soil corrosivity tests were performed on eleven samples. The tests were performed for us by M.J. Schiff & Associates. The results are presented on Plates A-8.1 through A-8.6.

Re: Soil Corrosivity Tests
Playa Vista Development
Los Angeles, California
Your #AE-88473, MJS&A #89012

Gentlemen:

Laboratory tests have been completed on 11 soil samples we selected from your exploratory borings for the subject marina on Lincoln Boulevard at Ballona Creek. Development of the marina will require the installation of retaining walls. The walls could consist of either gravity walls or driven sheet piling. The purpose of these tests was to determine if these soils may have deleterious effects on the sheet piling, concrete structures and foundations, steel piles and underground utilities.

The electrical resistivity of each sample was measured in its as-received condition and again with distilled water added to create the standardized condition of saturation. Resistivities are at about their lowest value when the soil is saturated. The samples were chemically analyzed for the major anions and cations, and pH was measured. Sulfides and oxidation-reduction (redox) potentials were also measured on samples containing peat or a sulfur odor. Results are shown in Table 1.

One of the most useful factors in determining soil corrosivity is electrical resistivity. The electrical resistivity of a soil is a measure of its resistance to the flow of electrical current. Corrosion of buried metal is an electrochemical process in which the amount of metal loss due to corrosion is directly proportional to the flow of electrical current (DC) from the metal into the soil. A soil's resistivity decreases and therefore its corrosivity increases primarily as its moisture and chemical contents increase.

A commonly accepted correlation between electrical resistivity and corrosivity toward ferrous metals is:

<u>Soil Resistivity in ohm-centimeters</u>	<u>Corrosivity Category</u>
0 to 1,000	severely corrosive
1,000 to 2,000	corrosive
2,000 to 10,000	moderately corrosive
over 10,000	mildly corrosive

February 28, 1989
Page 2

Electrical resistivities measured in the laboratory with as-received moisture content were in moderately corrosive to severely corrosive categories. However, most of the samples were in the severely corrosive category. When saturated, all resistivities were in the severely corrosive category. Some soils were at or near their most corrosive moisture content as-received. The wide variation in soil resistivity can create concentration type corrosion cells that increase corrosion rates above what would be expected from the soil characteristics alone.

pH values varied from 7.2 to 8.3 which is neutral to moderately alkaline. This is not significant in evaluating corrosivity in this case.

The chemical content of the samples was very high, except for the samples from borings 14 and 17. As might be expected, sodium chloride was the predominant compound. Chloride ions are particularly corrosive to ferrous metals and in such high concentrations can overcome the corrosion inhibiting effect of concrete on reinforcing steel.

Sulfates were fairly high in a few samples. Sulfates at concentrations above about 1000 ppm are moderately aggressive towards concrete.

Sulfides, which are aggressive to copper, showed a strong reaction in a qualitative test on two deep samples containing organic material. The low or negative redox potentials indicate reducing conditions in which anaerobic, sulfide producing bacteria thrive.

We classify this site as severely corrosive to ferrous metals, possibly aggressive toward copper, and moderately deleterious toward concrete. The following corrosion control measures are recommended.

Underground steel utilities should be blasted and given a high quality protective coating such as extruded polyethylene, 50 mil tape coating system over primer, or hot applied coal tar enamel or tape.

Buried steel piping should be electrically insulated from dissimilar metals, cement-mortar or concrete coated steel, and above ground steel pipe. Underground steel pipe should be bonded for electrical continuity if rubber gasketed, mechanical, grooved end, or other nonconductive type joints are used.

Cathodic protection is strongly recommended for underground steel utilities.

The use of nonmetallic materials should be considered.

It is assumed that prestressed concrete piles will contain at least 8 sacks of type 2 prestress cement per cubic yard of concrete and a water/cement ratio not exceeding 0.45. With such a mix, concrete cover should be at least 2 inches thick over embedded steel from a corrosion viewpoint. Solid steel lifting lugs are recommended to prevent groundwater from wicking into the pile interior. If wire rope lifting lugs are used, they should be carefully drilled out 1.5 inches deep and the hole filled with epoxy.

LeROY CRANDALL
MJS&A #89012

February 28, 1989
Page 3

Steel piles are most susceptible to corrosion in the upper portions where oxygen is available to support corrosion. Further, the portion of steel piles embedded in concrete pile caps forms a dissimilar environment corrosion cell with the steel in the soil. In this cell the steel in soil is anodic (corroding) to the steel in the cap (protected).

Steel piles may be protected by coating them with coal tar epoxy. Although this tough coating may be damaged somewhat during driving, it will provide a great deal of protection. Some corrosion can be tolerated without appreciably affecting the pile's structural strength. The coating need not be applied to those portions of the piles driven into undisturbed soil permanently below the water table where oxygen is not available.

A coating is important on portions of the piles to be embedded in concrete in order to minimize the dissimilar environment effect on non-embedded steel. Significant coating damage should be repaired after driving where the piles will be embedded in concrete and on several lineal feet of adjacent pile. It would be desirable to prevent metal to metal contact between the piles and reinforcing steel.

The interior of pipe piles may be protected by filling with concrete or sealing both ends.

For protection of reinforcing steel, dense concrete mixes with a water/cement ratio not exceeding 0.45, will minimize concrete permeability. A silica fume additive can be used to increase the resistivity of the concrete and reduce chloride and oxygen diffusion into the concrete. A calcium nitrite corrosion inhibiting additive, such as W. R. Grace DCI, can be used to reduce rebar corrosion. Fusion bonded epoxy coating of the reinforcing steel, in combination with waterproofing of the soil side concrete, possibly in conjunction with cathodic protection, may also be considered.

Concrete in contact with these soils should be made with type 2 cement.

Concrete cover over reinforcing steel in concrete contacting these soils should be at least 2 inches thick if placed against forms and 3 inches thick if placed against the earth.

Steel tie-back rods for retaining walls may be protected by using corrosion inhibiting grease and installing in nonmetallic sleeves or conduits to prevent soil contact, by encasing rods in concrete or grout, cathodic protection, or a combination of these.

Steel sheet piling should be coated with a suitable dielectric coating, such as coal tar epoxy, and can be cathodically protected. If cathodically protected, the piling should be made electrically continuous.

LeROY CRANDALL & ASSOCIATES
MJS&A #89012

February 28, 1989
Page 4

Cast or ductile iron pipe, valves, and fittings should be encased in an 8 mil polyethylene tube or wrap per AWWA Standard C105/ANSI 21.5. Underground iron pipe should be electrically insulated from dissimilar metals, cement-mortar or concrete coated iron, and above ground iron pipe.

Due to the high chlorides and dissimilarities in the shallow soils, buried copper tubing should be coated with plastic pipe wrapping tape over primer and cathodically protected. Insulation over buried hot water copper tubing should be carefully sealed. If cathodically protected, insulating joints should be installed just above the floor in all risers from underground.

No special precautions are required for plastic utilities placed underground from a corrosion viewpoint. However, any iron valves or fittings should be protected as mentioned above.

Sand would be better than the existing soils for bedding and backfill of metallic piping from a corrosion standpoint.

Where metallic pipelines penetrate concrete structures such as building floors or walls, plastic sleeves, rubber seals, or other dielectric material should be used to prevent pipe contact with the concrete and reinforcing steel.

On any type of pipe, bare steel appurtenances such as bolts, joint harnesses, or flexible couplings should be coated with a coal tar or rubber based mastic after assembly.

The scope of this study was limited to a determination of soil corrosivity and its general effects on materials likely to be used for construction. If the architect and/or engineers desire more specific information, designs, specifications, or review of design, we will be happy to work with them as a separate phase of this project.

Respectfully submitted,
M. J. SCHIFF & ASSOCIATES

APPENDIX B
CONE PENETRATION TESTS

The five Cone Penetration Tests (CPTs) were performed to depths of approximately 66 to 72 feet below grade at the locations shown on Plate 1. The testing was performed for us by Pioneer Drilling Company.

The CPT consists of pushing a cone-tipped probe into a soil deposit and recording the resistance of the soil to that penetration. The test was conducted in general accordance with ASTM Test Designation D-3441. The test equipment consists of a cone assembly equipped with a piezometer at the tip, a series of hollow sounding rods, a hydraulic frame to push the cone and rods into the soil, an electronic data processing unit, and a truck to transport the test equipment and provide the needed thrust capacity.

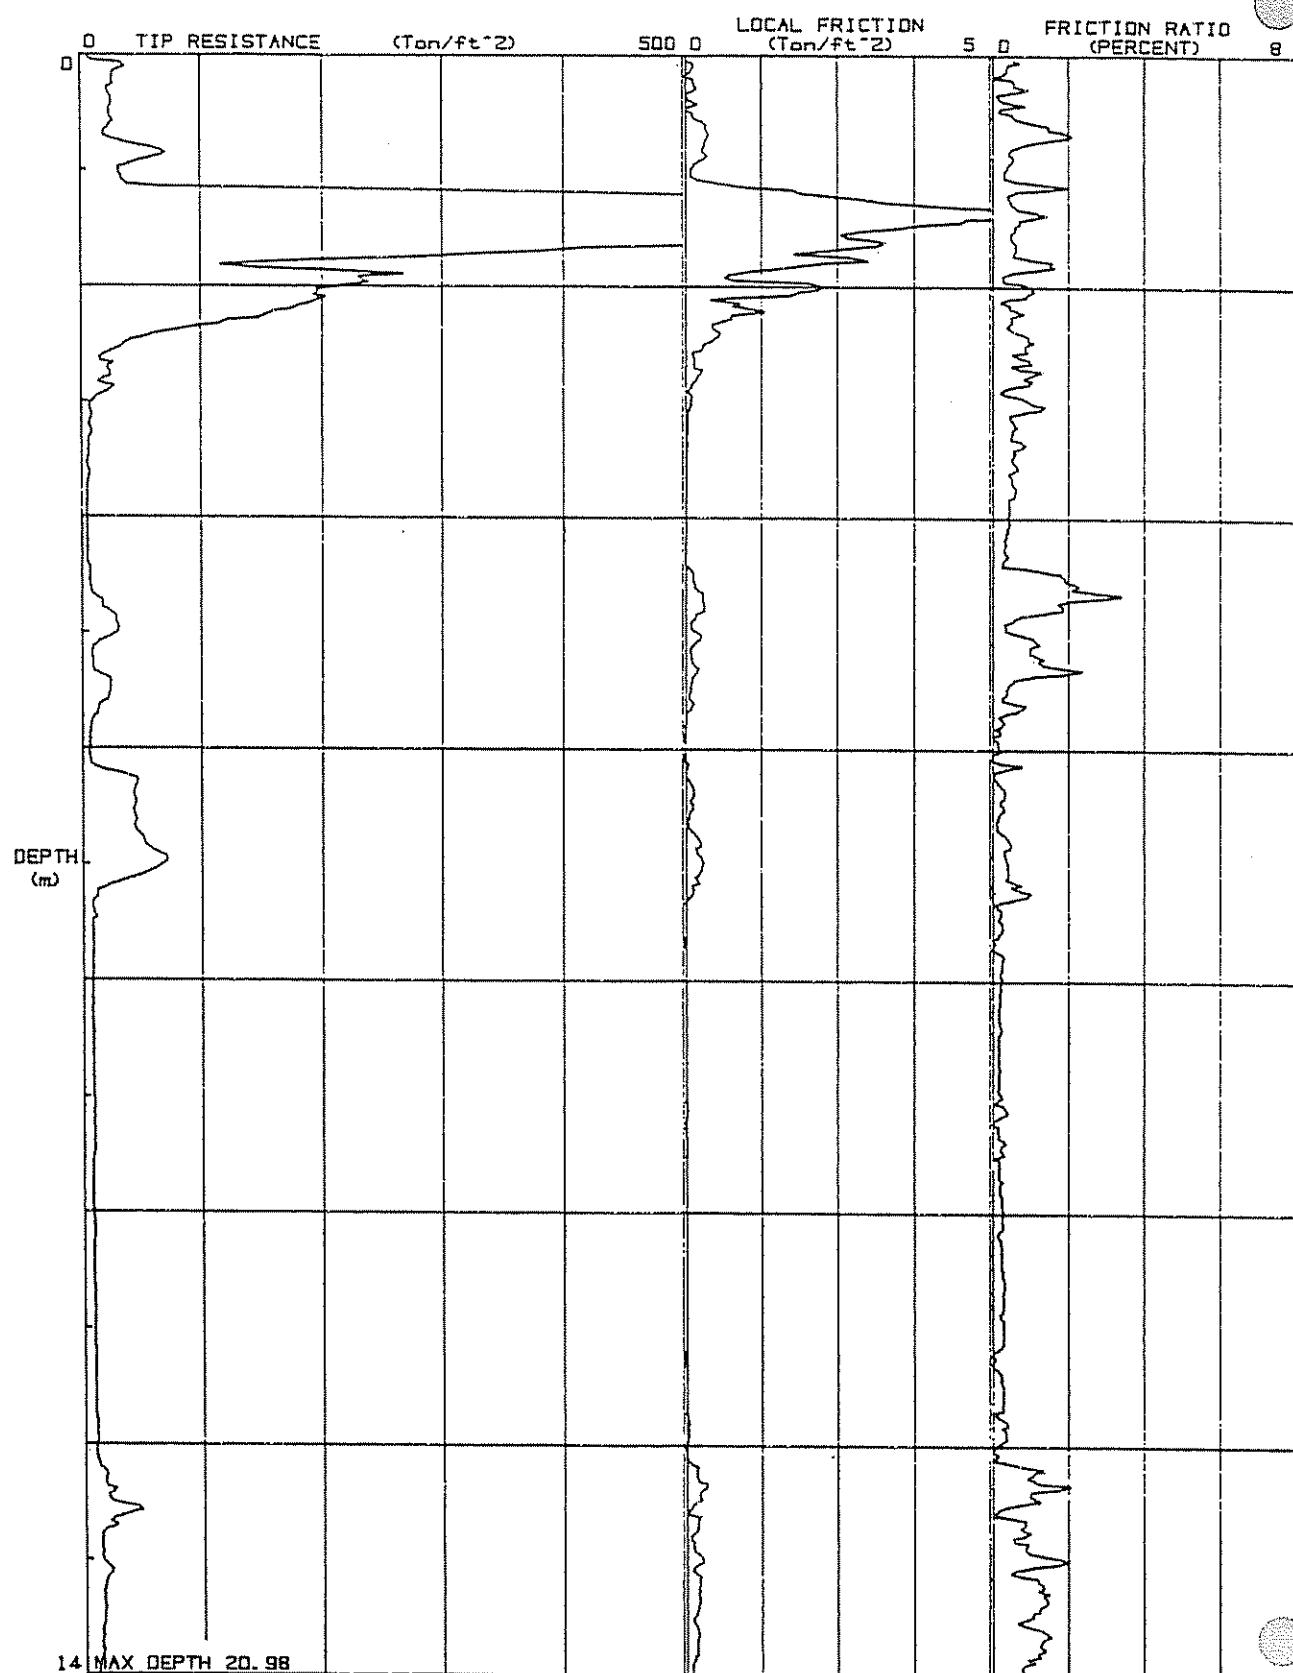

The probe ("penetrometer") consists of a conical tip with a 60 degree apex angle and a cylindrical friction sleeve. The interior of the device is instrumented with strain gauges allowing simultaneous measurements of cone and sleeve resistance during penetration. The pressure due to the head of ground water table above the tip of the cone and any excess pore water pressures generated due to penetration of the cone into the soils can be measured by an electronic piezometer installed at the tip of the cone. Electric signals from the strain gauges and the piezometer are transmitted by cable to the data processing unit. The cone assembly used on this project has a cross-sectional area of 10 square centimeters, and a sleeve surface area of 150 square centimeters. The penetrometer system has a total thrust capacity of about 20 tons.

Output quantities for the cone tip penetration resistance and (local) sleeve friction are simultaneously recorded in units of tons per square foot (tsf) versus depth in units of meters (m). The pore pressure (in units of pounds per square inch) is also recorded versus depth. The recording apparatus is also designed to calculate and record the ratio of friction resistance to tip resistance (known as the friction ratio) and the ratio of pore pressure to tip resistance (known as the pore pressure ratio). Plots of these five quantities are presented on Plates B-1.1 through B-1.5. The cone tip resistance and friction ratio were evaluated using published literature in order to classify the subsurface soils. The interpreted results of the tests are presented on Plates B-2.1 through B-2.5.
