Abstract

1

A multi-year study in the Sacramento-San Joaquin Delta system was carried out to exam-2 ine the relationship between the survival of out-migrating Chinook salmon Oncorhynchus 3 tshawytscha and the amount of water exported from the system by the two major pumping 4 stations in the southern portion of the Delta. Paired releases of groups of coded-wire-tagged 5 juvenile late-fall run Chinook salmon were made at two locations in the Delta, one in the 6 main stem Sacramento River and one in the interior portion of the Delta where they were 7 more likely to be directly affected by the pumping stations. Shortly after release, fish were 8 recovered downstream by a mid-water trawl, and, over a two to four year period, fish were 9 recovered in samples of ocean fishery catches and from spawning ground surveys. A Bayesian 10 hierarchical model for the recoveries was fit which explicitly accounted for between release 11 variation in survival and capture probabilities as well as sampling variation in the recoveries. 12 Survival of the interior Delta releases was considerably lower than the survival of main steam 13 releases (mean ratio of survival probabilities was 0.35). The ratio of survival probabilities 14 was negatively associated with water export levels, but various model selection criteria gave 15 more, or nearly equal, weight to simpler models which excluded exports. The signal-to-noise 16 ratio, as defined in terms of the export effect relative to environmental variation, however, 17 was very low, and could explain indeterminacy in the results of model selection procedures. 18 Many more years of data would be needed to more precisely estimate the export effect. 19 Whatever the factors are that adversely affect survival through the interior Delta, to deter-20 mine the overall effect on out-migrating Sacramento river Chinook salmon the fraction of 21 out-migrants that enter the interior Delta needs to be estimated. 22

²³ 1 Introduction

Juvenile Chinook salmon (Oncorhynchus tshawyschta) survival experiments have been con-24 ducted in the Sacramento-San Joaquin Delta of California since the early 1970s (Kjelson, et 25 al. 1981 and 1982; Kjelson and Brandes 1989; Brandes and McLain 2001). The experiments 26 have involved the release, at multiple locations throughout the Delta, of marked and tagged 27 hatchery-reared juvenile salmon followed by later recovery of these salmon. Survival of ju-28 venile salmon through the Delta is of particular interest because of the Delta's role in water 29 management in California. Two large pumping facilities, the Central Valley Project's C. W. 30 "Bill" Jones Pumping Plant (CVP) and the State Water Project's Harvey Banks Pumping 31 Plant (SWP), are located in the south Delta (Figure 1) and provide water, to over 23 million 32 people, for municipal, agricultural and domestic purposes throughout central and southern 33 California. The Delta is critical for Sacramento-San Joaquin origin salmon survival as all 34 juvenile salmon must migrate through the Delta to reach the Pacific Ocean. There are two 35 races of Central Valley Chinook salmon listed under the Endangered Species Act, winter run 36 as endangered (NMFS 1997) and spring run as threatened, with the other two races, fall and 37 late-fall run, considered species of concern. The role of CVP and SWP exports on juvenile 38 salmon survival through the Delta is of great interest to managers and stake-holders and 39 this interest has been a primary reason for the salmon survival experiments. 40

Previous analyses of some of these survival experiments, using juvenile fall run Chinook salmon (Kjelson, et al. 1981; Brandes and McLain 2001; Newman and Rice 2002; Newman 2003) which out-migrate through the Delta from March through June (Yoshiyama, et al. 1998), have suggested that survival is negatively associated with water exports. These analyses included data from a very spatially-dispersed set of release locations where many variables other than export levels potentially affected survival.

In this paper we analyze release-recovery data from a more narrowly focused study of ex-47 port effects, where factors other than exports were to some degree controlled for by temporal 48 pairing of releases. Paired releases of juvenile late-fall run Chinook salmon were made simul-49 taneously in the interior Delta and in the main stem of the Sacramento River downstream of 50 the Delta Cross Channel and Georgiana Slough (Figure 1). The interior Delta is an area of 51 the Delta that out-migrating juvenile salmon can enter from the Sacramento River through 52 either the Delta Cross Channel, when the Delta Cross Channel gates are open, or Georgiana 53 Slough. Fish released directly into the interior Delta are presumably more vulnerable to the 54 influence of the CVP and SWP pumping facilities than fish released in the main stem. In 55 contrast to fall run experiments (Newman and Rice 2002), the temporal pairing of releases 56 controlled for the effects of all factors other than release location and exports on survival. 57 One limitation of the study, however, is that levels of exports cannot be fixed or controlled 58 by researchers due to the precedence of water demands. Another limitation is that the over-59 all effect of exports on out-migrating salmon cannot be determined without knowing the 60 proportion of out-migrating salmon that enter the interior Delta. 61

⁶²Brandes and McLain (2001) analyzed paired release-recovery data that included releases ⁶³of late-fall run fish and fall run fish. Their analysis procedure was to first calculate freshwa-⁶⁴ter recovery fractions (adjusted for estimates of capture efficiency) and then to regress the ⁶⁵fractions against export levels. Based on the data available at the time, they found a sta-⁶⁶tistically significant negative association between the survival of Georgiana Slough releases ⁶⁷relative to the survival of Ryde releases and export levels (Figure 1).

⁶⁸ One purpose of this paper is to update the analyses of Brandes and McLain (2001)

incorporating the since-gathered data but only using late-fall run stock. Late-fall run fish 69 are potential surrogates for winter run salmon (Brandes and McLain 2001), since both runs 70 out-migrate from November through May (Yoshiyama, et al. 1998). A second purpose is 71 to compare results for the Brandes and McLain approach with results based on Bayesian 72 hierarchical models (Carlin and Louis 1996; Gelman, et al. 2004; for a fisheries release-73 recovery application, Newman 2003). Hierarchical models offer several potential advantages 74 for analyzing multi-release studies. One advantage is parsimony; rather than estimating 75 release-pair specific effects independently, e.g., n independent estimates of relative survival 76 for n release pairs, a single distribution for the effects underlying the results for all release 77 pairs is specified. Another advantage is that such a random effects distribution characterizes 78 the environmental variation in survival probabilities, and the hierarchy makes this variation 79 distinct from sampling variation. A third advantage is that a hierarchical model provides 80 a sensible means of combining data from multiple year studies, in this case multiple sets of 81 paired releases with associated recoveries, e.g., giving release-pairs with fewer fish released 82 less weight than those with more fish released. 83

The paired release-recovery experiment design and the statistical models used for analysis are described in Section 2. Results are given in Section 3. We close with a discussion (Section 4) of the management implications of the results.

$_{\scriptscriptstyle 87}$ 2 Methods

88 2.1 Data

The paired release-recovery data, including numbers released, numbers recovered at various 89 locations, and the water export levels at time of release, are given in Table 1. Fifteen paired 90 groups of juvenile late-fall run Chinook salmon yearlings (mean size > 100 mm), reared at 91 Coleman National Fish Hatchery, were released between 1993 and 2005 during the months of 92 December and January. At the hatchery, each fish had its adipose fin clipped and a coded-93 wire-tag was inserted into its snout; to read such tags after implantation requires sacrificing 94 the fish. The tag codes were batch-specific, i.e., the same codes were used for thousands of 95 fish, with unique tag codes for each release location. The fish were trucked from the hatchery 96 to the interior Delta (Georgiana Slough) and the main stem Sacramento River (at Ryde or 97 Isleton) (Figure 1), and releases were made at both locations with a day or two. 98

Within a few weeks of release, recoveries were made in freshwater by a mid-water trawl 99 operating near Chipps Island (Figure 1). The trawl was towed at the surface almost daily 100 for four to six weeks after the fish were released. Typically, ten, twenty minute tows were 101 made each day between roughly 7 AM and noon. Juvenile fish were also recovered at fish 102 facilities located in front of the pumping plants at CVP and SWP. These recovered salmon 103 were transported by truck and released at locations north of the pumps and nearer to the 104 main stem of the Sacramento River upstream of Chipps Island, where they could potentially 105 be caught by the mid-water trawl at Chipps Island. Then over a three to four year period, 106 adult fish were recovered from samples of landings from ocean fisheries. The total number of 107 ocean fishery recoveries, summed over many landing areas and years, was estimated from a 108

spatially and temporally stratified random sample of landings and catches. The percentage 109 of ocean catch that is sampled is roughly 20-25%. Additional recoveries of adult fish were 110 made in freshwater fisheries, at hatcheries, and on spawning grounds (inland recoveries). 111 The expanded ocean and inland recoveries were retrieved from a web-based database query 112 system administered by Pacific States Marine Fisheries Commission (www.rmpc.org). The 113 straying proportions, i.e., the fraction of inland recoveries that were not recovered at Coleman 114 National Fish Hatchery, for Georgiana Slough and Ryde releases varied considerably between 115 release pairs, but within release pairs the proportions were quite similar. 116

The combined water export levels, hereafter referred to as exports, from both the SWP 117 and the CVP were averaged over a three day period starting the day after release in Georgiana 118 Slough. The choice of three days was somewhat arbitrary, although linear correlations of 119 three day average export levels with averages for 10 and 17 days were quite high (r=0.94)120 for 10 days and r=0.91 for 17 days). There is a certain degree of imprecision to defining an 121 export variable with regard to fish outmigration because some fish take longer to out-migrate 122 than others and the degree of exposure to the area influenced by the pumps will vary; e.g., 123 the Georgiana Slough release in group 1 had one recovery at the SWP fish facility three 124 months after release. Furthermore, export levels are not necessarily constant, even within 125 a three day period, and day to day variation in export level is not captured by the use 126 of an average. Water volumes entering the interior Delta are also affected by the position 127 of the Delta Cross Channel gates, which when open increase the flow of water from the 128 Sacramento River into the interior Delta. The gates were open on the day of the Georgiana 129 Slough releases in the first two years of the study (1993 and 1994), and for one of the 1999 130 releases (Group 10), but otherwise closed for all other releases. Recognizing that it might be 131 the amount of exports relative to total inflow from the Sacramento River (at Freeport) that 132

could be more important than absolute exports, the export to flow ratio was also examined as a covariate; the relationship between the ratios and the absolute values, however, was positive and linear (r=0.83).

¹³⁶ 2.2 Assumptions and notation

Within and between releases, the fate of an individual fish, e.g., live or die, caught or not, was 137 assumed independent of the fate of any other fish. For all fish released from one location at 138 the same time, the survival and capture probabilities were assumed identical. In recognition 139 of the paired release aspect of the studies, we further assumed that within a release pair 140 the probability of capture at Chipps Island, and the recovery probabilities (a complicated 141 combination of survival and capture probabilities) in the ocean fishery and inland areas were 142 identical. For example, for release pair 1 (Table 1) the capture probability for a Ryde fish or 143 a Georgiana Slough fish that has survived to Chipps Island is the same, but that probability 144 can differ from that for release pair 2. 145

We further assumed that only fish released in Georgiana Slough were affected by exports. 146 Ryde is located 2.5 miles downstream of the location on the main stem where water is diverted 147 into the Georgiana Slough and releases at Ryde are further removed geographically from the 148 export facilities. However, for two years there were sizeable numbers of Ryde fish recovered 149 at the fish facilities (Table 1); these were potentially situations where flood tides carried 150 some of the Ryde releases into the interior Delta at some upstream or downstream locations, 151 e.g., Three Mile Slough (Figure 1), a channel several miles downstream that connects the 152 Sacramento and San Joaquin Rivers in the Delta. 153

For a given release pair t, the numbers released at Ryde and Georgiana Slough are

denoted $R_{Ry,t}$ and $R_{GS,t}$ and the associated recoveries at Chipps Island are $y_{Ry\to CI,t}$ and $y_{GS\to CI,t}$. Expanded ocean recoveries are $\hat{y}_{Ry\to Oc,t}$ and $\hat{y}_{GS\to Oc,t}$, and similarly expanded inland recoveries are $\hat{y}_{Ry\to IL,t}$ and $\hat{y}_{GS\to IL,t}$. Recovery fractions, defined as the ratios of number of recoveries to number released, will be denoted \hat{r} , with subscripts indicating release and recovery locations; e.g., $\hat{r}_{Ry\to Oc,t} = \hat{y}_{Ry\to Oc,t}/R_{Ry,t}$. Combined recovery fractions for more than one recovery location are denoted similarly; e.g., $\hat{r}_{Ry\to CI+Oc+IL,t} = (y_{Ry\to CI,t}+\hat{y}_{Ry\to Oc,t}+$ $\hat{y}_{Ry\to IL,t})/R_{Ry,t}$.

Notation for the probability that a Ryde release is recovered at Chipps Island is $r_{Ry\to CI,t}$ 162 and the recovery probability for ocean fisheries and inland recoveries combined is $r_{Ru\to Oc+ILt}$. 163 The corresponding probabilities of recovery for Georgiana Slough releases are denoted $\theta_t r_{Ry \to CI,t}$ 164 and $\theta_t r_{Ry \to Oc,t}$, where θ_t is a release pair-specific constant. Given the assumption that within 165 a release pair, the capture probabilities at Chipps Island are the same, θ_t is the ratio of the 166 survival probability between Georgiana Slough and Chipps Island to the survival probability 167 between Ryde and Chipps Island. How θ_t relates to export levels is the primary management 168 question. 169

¹⁷⁰ 2.3 Non-Bayesian, non-hierarchical models

Two non-hierarchical models were fit. Both somewhat mimic Brandes and McLain's (2001) analyses in that a two step procedure was used: (a) an estimate of θ_t is calculated; (b) the estimate is regressed against exports. The first model is quite similar to Brandes and McLain's analysis in that only recoveries at Chipps Island are used, i.e., θ_t is estimated as the the ratio of recovery fractions at Chipps Island for Georgiana Slough and Ryde releases,

$$\hat{\theta}_{1,t} = \frac{\hat{r}_{GS \to CI,t}}{\hat{r}_{Ry \to CI,t}}$$
(1)

¹⁷⁷ In contrast to Brandes and McLain (2001), recoveries were not scaled by estimated gear ¹⁷⁸ efficiency, because of the assumption that capture probabilities were identical within a release ¹⁷⁹ pair. A simple linear regression model using standardized exports was fit:

$$\hat{\theta}_{1,t} \sim \operatorname{Normal}\left(\beta_0 + \beta_1 E x p_t^*, \sigma^2\right), \qquad (2)$$

where $Exp_t^* = (Exp_t - \overline{Exp})/s_{Exp}$, Exp_t is the exports at time t, \overline{Exp} is the average export level, and s_{Exp} is the standard deviation of exports. Assuming independence and identical probabilities of survival and capture for all fish in a single release, the number of fish recovered at Chipps Island is a binomial random variable, e.g., $y_{Ry\to CI,t} \sim \text{Binomial}(R_{Ry,t}, r_{Ry\to CI,t})$. Given $R_{Ry,t}$ and $y_{Ry\to CI,t}$, $\hat{r}_{Ry\to CI,t}$ is the maximum likelihood estimate (mle) of $r_{Ry\to CI,t}$; similarly, $\hat{r}_{GS\to CI,t}$ is the mle of $\theta_t r_{Ry\to CI,t}$, and $\hat{\theta}_{1,t}$ is the mle for θ_t based on Chipps Island recoveries alone.

For the second non-hierarchical model, θ_t was estimated using Chipps Island, ocean, and inland recoveries combined,

190

199

$$\hat{\theta}_{2,t} = \frac{\hat{r}_{GS \to CI + Oc + IL, t}}{\hat{r}_{Ry \to CI + Oc + IL, t}}.$$
(3)

Implicit to this calculation is the assumption that within a release pair the Chipps Island 191 capture probabilities, the ocean recovery probabilities, and the inland recovery probabilities 192 are identical. If total ocean and inland recoveries were known exactly and not estimated, 193 the joint distribution of Chipps Island recoveries and combined ocean and inland recoveries 194 would be multinomial, and $\hat{\theta}_{2,t}$ would be the mle for θ_t . However, with expanded recoveries, 195 the distribution is more complex. To account for differences in sampling variation and to 196 somewhat duplicate the hierarchical model, a weighted regression of the log of $\hat{\theta}_{2,t}$ against 197 standardized exports was fit: 198

$$\ln\left(\hat{\theta}_{2,t}\right) \sim \operatorname{Normal}\left(\beta_0 + \beta_1 E x p_t^*, s e_{\ln\left[\hat{\theta}_{2,t}\right]}^2 \sigma^2\right).$$
(4)

The weights were the inverse of the square of the standard errors of $\ln[\hat{\theta}_{2,t}]$, $se_{\ln[\hat{\theta}_{2,t}]}$, which were calculated using the delta method (cf Section 10.5, Stuart and Ord, 1987). The log transformation ensures that $\theta_{2,t}$ remains non-negative.

The primary inferential aim, for both models (Equations 2 and 4), is to estimate the slope coefficient β_1 and its standard error.

205 2.4 Hierarchical models

Hierarchical models (Carlin and Louis 1996) consist of two or more levels, each level accounting for a different type of variation. For these data, the first level accounts for sampling variation in the recoveries conditional on survival and capture probabilities, while the second level accounts for between release pair variation in the survival and capture probabilities. The second level reflects what is sometimes referred to as random effects. The prior distributions for the fixed and unknown parameters of the model (in the second level) make up the third level of the model.

213 2.4.1 Bayesian hierarchical model

A Bayesian hierarchical model (BHM) was formulated for the joint distribution of Chipps Island recoveries and the combined ocean and inland recoveries. The statistical distributions for each of the levels of the hierarchical model are shown below. The first level distributions are conditional on the second level variables, and similarly the second level is conditional on the third level. 219 Level 1:

220

$$y_{GS \to CI,t}, \hat{y}_{GS \to Oc+IL,t} \sim \text{Multinomial} \left(R_{GS,t}, \theta_{3,t} r_{Ry \to CI,t}, \theta_{3,t} r_{Ry \to Oc+IL,t} \right)$$
(5)

221
$$y_{Ry \to CI,t}, \hat{y}_{Ry \to Oc+IL,t} \sim \text{Multinomial}(R_{Ry,t}, r_{Ry \to CI,t}, r_{Ry \to Oc+IL,t})$$
 (6)

222 Level 2:

$$\ln(\theta_{3,t}) \sim \operatorname{Normal}\left(\beta_0 + \beta_1 E x p^*, \sigma_\theta^2\right)$$
(7)

224
$$\operatorname{logit}(r_{Ry \to CI,t}) \sim \operatorname{Normal}\left(\mu_{r_{Ry \to CI}}, \sigma_{r_{Ry \to CI}}^2\right)$$
 (8)

$$logit(r_{Ry \to Oc+IL,t}) \sim Normal\left(\mu_{r_{Ry \to Oc+IL}}, \sigma^2_{r_{Ry \to Oc+IL}}\right)$$
(9)

226 Level 3:

227

228

 $\beta_0, \beta_1, \mu_{Ry \to CI}, \mu_{Ry \to Oc+IL} \sim \text{Normal} (0, 1.0E + 6)$ (10)

$$\sigma_{\theta}, \sigma_{r_{Ry \to CI}}, \sigma_{r_{Ry \to Oc+IL}} \sim \text{Uniform}(0, 20)$$
 (11)

As noted previously the joint distributions for Chipps Island recoveries and combined expanded ocean and inland recoveries cannot be multinomial due to estimation error in the expansions, thus the Level 1 formulation is an approximation. The log transformation of $\theta_{3,t}$ (in the Level 2 model) ensures that $\theta_{3,t}$ is non-negative. The logit transformations at Level 2 bounds $r_{Ry\to CI,t}$ and $r_{Ry\to Oc+IL,t}$ between 0 and 1; however, the resulting probabilities are so small that log transformations would have the same practical effect.

In contrast to the likelihood framework, the inferential objective in the Bayesian setting is to calculate the posterior distribution for the unknown parameters (Gelman, et al. 2004), i.e., to calculate

$$p(\Theta|Data) \propto p(Data|\Theta)p(\Theta)$$

where Θ is the vector of unknown constants, such as β_0 and β_1 , and unknown random variables, such as θ_t , and $p(\Theta)$ is the prior distribution (here defined by Level 3). In this case primary interest is in the posterior distribution for β_1 and the probability that β_1 is negative is a measure of the degree of a negative association between exports and the relative survival of Georgiana Slough releases.

244 2.4.2 Sensitivity analysis

Sensitivity of the BHM to the choice of distributions and functional forms was assessed by alternative formulations for each level. At Level 1, to allow for possible dependence between fish within a release as well as extra-multinomial variation due to the fact that ocean and inland recoveries are sample expansions, negative binomial distributions were used for the Chipps Island and expanded ocean and inland recoveries from a given release. For example, the negative binomial model for recoveries at Chipps Island of releases from Ryde is the following.

$$y_{Ry \to CI} \sim \text{Negative Binomial}\left(k_{CI}, \frac{k_{CI}}{R_{Ry}r_{Ry \to CI} + k_{CI}}\right)$$

where k_{CI} is a non-negative constant that affects the degree of overdispersion (relative to a Poisson, or indirectly a Binomial, random variable). The larger k_{CI} is, the less the overdispersion.

At Level 2, several alternative models were fit. One model removed exports from the model for $\ln(\theta_{3,t})$. A second used a logistic transformation of $\theta_{3,t}$, ensuring $0 \le \theta_{3,t} \le 1$, i.e., the Georgiana Slough to Chipps Island survival probability cannot exceed Ryde to Chipps Island survival probability. A third alternative was a multivariate normal distribution for the joint distribution of $\theta_{3,t}$, $r_{Ry\to CI,t}$, and $r_{Ry\to Oc+IL,t}$, which allowed for correlation among these parameters within each release pair. In particular, $\theta_{3,t}$ was log transformed and, largely to facilitate fitting, an extension of a logistic model was used to transform $r_{Ry\to CI,t}$ and $r_{Ry \to Oc+IL,t}$, i.e., dropping the subscript t to reduce notation,

$$\begin{array}{c} {}_{264} \end{array} \left[\begin{array}{c} \theta^{1} \\ \theta^{2} \\ \theta^{3} \end{array} \right] \sim \mathrm{MVN} \left(\left[\begin{array}{c} \beta_{0} + \beta_{1} E x p^{*} \\ \mu_{Ry \to CI} \\ \mu_{Ry \to Oc} \end{array} \right), \Sigma = \left[\begin{array}{c} \sigma_{1}^{2} & \sigma_{1,2} & \sigma_{1,3} \\ \sigma_{2,1} & \sigma_{2}^{2} & \sigma_{2,3} \\ \sigma_{3,1} & \sigma_{3,2} & \sigma_{3}^{2} \end{array} \right] \right)$$

265 where

$$\theta^1 = \ln(\theta_3)$$

$$\theta^2 = \ln\left(\frac{r_{Ry\to CI}}{1 - r_{Ry\to CI} - r_{Ry\to Oc+IL}}\right)$$

$$\theta^3 = \ln\left(\frac{r_{Ry\to Oc+IL}}{1 - r_{Ry\to CI} - r_{Ry\to Oc+IL}}\right).$$

A fourth alternative was to use the fraction of exports relative to total river flow, exports/flow, instead of the absolute level of exports. A fifth alternative was to remove random effects, i.e., the Level 2 models were deterministic.

For Level 3, various prior distributions were tried for the Level 2 fixed parameters. We used the inverse gamma distributions instead of uniform distributions (equation 11) for the variances of the random effects, i.e., σ_{θ}^2 , $\sigma_{r_{Ry \to CI}}^2$, and $\sigma_{r_{Ry \to Oc+IL}}^2$. For the multivariate normal model, an inverse Wishart distribution was used as the prior for the variance-covariance matrix, Σ .

Not all possible combinations of models for each level were fit. During the fitting process it became clear that certain options at one level led to clearly poor fitting models; e.g., removing random effects at level 2 led to a drastic drop in model fit no matter what options were selected at other levels.

281 2.4.3 Model fitting, assessment, and comparison

To fit the BHMs we used the program WinBUGS (Lunn, et al. 2003), which generated samples from the joint posterior distribution for the parameters, random effects, and expected numbers of recoveries. WinBUGS is based on a technique known as Markov chain Monte Carlo, MCMC (Gilks, Richardson, and Spiegelhalter 1996), which is a computer simulation method where samples are generated from a Markov chain which has a limiting distribution equal to the distribution of interest, in this case the joint posterior distribution.

By a limiting distribution it is meant that the samples do not initially come from the 288 desired distribution, but once "enough" samples are generated, the so-called burn-in period, 289 all additional samples do come from the desired distribution. WinBUGS includes measures, 290 e.g., the Brooks-Gelman-Rubin statistic (Brooks and Gelman, 1998), based upon the results 291 of simulating from multiple Markov chains with differing initial values, for determining an 292 adequate burn-in period. Informally stated, given widely different starting values, the point 293 at which the chains begin to overlap, i.e., begin mixing, is the necessary burn-in period, 294 presumably the samples are coming from the limiting distribution and are not stuck at 295 some local mode of the posterior distribution. Values near 1.0 for the Brooks-Gelman-Rubin 296 statistic are evidence for convergence, with values below 1.1 often adequate (Gelman, et al. 297 2004, page 297). Three different chains, with differing initial values, were run in parallel and 298 the summary statistics are based on the pooled output following burn-in. 290

Goodness of model fit, for a given model, was assessed by calculating Bayesian P-values (Gelman, et al. 2004) for each of the observations. The P-value is the proportion of time a predicted value exceeds the observed value:

Bayesian P-value =
$$\frac{1}{L} \sum_{l=1}^{L} I(y_l^{pred} \ge y),$$

where I() is an indicator function equaling 1 when the condition inside () is met. The

predicted value, y_l^{pred} is found by simulating y from its probability distribution evaluated at the l^{th} parameter value in the MCMC sample. Ideally, the observed values will lie in the central portion of the simulated posterior predictive distribution, equally distributed around the median predicted values. A Bayesian P-value near 0 or 1 is indicative of a poor fit for the particular observation.

All the models were compared using the deviance information criterion, DIC (Spiegel-310 halter, et al. 2002). DIC can be viewed as a measure of overall model fit while penalizing 311 for model complexity. When comparing two models, the model with the lower DIC value is 312 estimated to have better predictive capabilities. Reversible jump MCMC (RJMCMC, Green 313 1995) was used to compare two models, one model with exports as a covariate (equation 314 (7)) and one without exports. Given the data, a set of models, and a corresponding set of 315 prior probabilities that a given model is the correct model (the prior model probability), 316 RJMCMC calculates posterior model probabilities. 317

318 3 Results

The recovery fractions for Georgiana Slough releases were consistently less than the fractions 319 for Ryde releases, with the exception of the fraction recovered at the fish facilities (Figure 320 2). The means of the ratios of recovery fractions equalled 0.26, 0.46, and 0.37 for Chipps 321 Island, ocean fisheries, and inland recoveries, respectively. Conversely, at the fish facilities, 322 Georgiana Slough releases were about 16 times more likely to be recovered. Also, the recovery 323 fraction of fish facility recoveries from the Georgiana Slough releases tended to increase, 324 from about 0.001 to 0.025, as exports went from 2000 cfs to 10000 cfs, although there was 325 considerable variability at any given level of exports (Figure 3). This suggested a higher 326

³²⁷ probability of ending up at the pumps with increasing exports. In contrast, the fraction of ³²⁸ Ryde releases ending up at the fish facilities, with group 3 an exception and a case with high ³²⁹ exports, was less than 0.001 (generally supportive of the assumption that Ryde releases were ³³⁰ unaffected by exports).

331 3.1 Non-hierarchical analyses

The release pair specific point estimates, $\hat{\theta}_1$ and $\hat{\theta}_2$, and corresponding standard errors are shown in Table 2. As expected, given the additional information provided by ocean and inland recoveries, the standard errors for $\hat{\theta}_2$ tended to be smaller than those for $\hat{\theta}_1$. That difference in standard errors was smaller for the most recent releases (groups 14 and 15) which likely have incomplete inland recovery information for older aged returns. Between release group variation in the estimates of θ_t was quite large, with values ranging from 0.13 to 0.80 (based on $\hat{\theta}_2$).

The fitted models of θ_t as a function of exports (equations 2 and 4) are the following:

341

$$\theta_{1,t} \approx \operatorname{Normal}\left(0.265 - 0.086 Exp_t^*, 0.18^2\right)$$
$$\ln\left(\hat{\theta}_{2,t}\right) \approx \operatorname{Normal}\left(-0.935 - 0.214 Exp_t^*, 3.88^2\right).$$

P-values for a one-sided test of significance of the slope coefficient for exports, with the alternative $H_1 : \beta_1 < 0$, are 0.05 for the $\hat{\theta}_1$ model and 0.04 for the $\ln(\hat{\theta}_2)$ model. Neither model fit particularly well, however; the R^2 values were 0.19 and 0.21 for the $\hat{\theta}_1$ and $\ln(\hat{\theta}_2)$ models, respectively.

346 3.2 Bayesian hierarchical model

For each model the burn-in time was 50,000 iterations, per chain, a further 150,000 iterations, 347 per chain, were carried out, and every tenth realization was used for the posterior samples. 348 The negative binomial model was an exception, due to somewhat slow computational speed. 349 burn-in was 50,000 iterations followed by 50,000 sample iterations. Evidence for conver-350 gence to the posterior distribution were Brooks-Gelman-Rubin statistics for all parameters 351 between 1.0 and 1.03, plots of the parameters for the three chains against simulation number 352 (traceplots) that showed considerable overlap and movement in chain values (consistent with 353 good mixing), and DIC values that were stable between different runs. 354

All the BHMs with a multinomial distribution for the observations (Level 1) and random 355 effects (Level 2) had nearly equal DIC values (Models #1-#6 in Table 3). Spiegelhalter, 356 et al. (2002) support the rule of thumb that models within 1-2 of the minimal DIC value 357 deserve consideration (as used by Burnham and Anderson (1998) for AIC). Notably, this set 358 included a model without exports. The results were robust to the choice of the prior for the 359 random effects standard deviation (σ), either uniform or inverse gamma. Either covariate, 360 exports or exports/flow, led to equivalent DIC values. Posterior means for $\theta_{3,t}$ were much 361 the same for these models. 362

The Bayesian P-values were essentially identical for these multinomial, random effect models. Fifty-three of the 60 total observations, 88%, had Bayesian P-values that fell inside of the middle 90% of posterior predictive distributions. There were too few observed recoveries (P=0.02 to 0.04) for two cases ($y_{Ry\to CI,1}$ and $y_{Ry\to CI,6}$), and too many observed recoveries (P=0.95 to 1.00) for five others ($y_{GS\to CI,5}, y_{GS\to CI,9}, y_{GS\to CI,12}, \hat{y}_{Ry\to Oc+IL,14}$ and $\hat{y}_{GS\to Oc+IL,14}$).

369

Replacing the multinomial distribution with the negative binomial distribution (Model

#7) or excluding random effects (Model #8) led to sizeable increases in DIC values (Table 371 3), especially for the latter model. Many of the Bayesian P-values for the non-random effects 372 model were close to 0 or 1. The negative binomial model's parameters, k_{CI} and k_{Oc} were 373 quite large (posterior means of 214 and 279), indicating little evidence for overdispersion.

Referring now to model #1 (although the results are nearly identical for models #2-#6), 374 the recovery probabilities for Ryde releases at Chipps Island were an order of magnitude 375 lower than those for the ocean fisheries and inland recoveries; the median for $r_{Ry\to CI}$ was 376 0.0004 versus 0.0038 for $r_{Ry \rightarrow Oc+IL}$. Given that recovery probabilities are the product of 377 survival and capture probabilities, $r_{Ry \to CI} \approx 0.0004$ seems reasonable for the Chipps Island 378 trawl based on independent estimates of Chipps Island trawl capture probabilities on the 379 order of 0.001 to 0.002 (Newman 2003). The correlations between θ , $r_{Ry\to CI}$, and $r_{Ry\to Oc}$, 380 on the transformed scales, were weakly positive: between θ and $r_{Ry\to CI}$ the posterior mean 381 for $\sigma_{1,2}$ was 0.21, between θ and $r_{Ry\to Oc} E[\sigma_{1,3}]$ was 0.18, and between $r_{Ry\to CI}$ and $r_{Ry\to Oc}$ 382 $E[\sigma_{2,3}]$ was 0.25. Thus, within a release pair, when survival was higher for one segment, it 383 tended to be higher for the other segments. 384

For all models with exports the posterior mean value for β_1 was negative, indicative of 385 a negative association between θ and exports. For Models #1-#5, $\Pr(\beta_1 < 0)$ ranged from 386 0.86 to 0.92. The variation in the relationship with exports, however, was quite large as both 387 the size of $E[\sigma_{\theta}]$ and the plot of predicted θ values against exports (Figure 4) indicate. While 388 the plot shows the decline in mean θ as exports increases (e.g., when exports are at 2000 cfs, 389 mean θ is 0.54, and when exports are at 10,000 cfs, mean θ is 0.34), the range of individual 390 values is very wide. Upper bounds on θ for export levels less than 7200 exceed 1.0, allowing 391 for the possibility that Georgiana Slough releases could occasionally have higher survival 392 than Ryde releases.

Given the similarity in DIC values amongst Models #1 - #6, and primary interest being 393 the effect of exports, reversible jump MCMC was applied to just two models differing only 394 in terms of the inclusion (Model #2) or exclusion (Model #6) of exports. The posterior 395 probability for the model including exports was only 1% compared to 99% probability for 396 the model without exports, thus apparently scant evidence for a relationship between θ and 397 exports. However, such results could be due to the low signal-to-noise ratio, as measured by 398 the posterior mean for β_1 to the posterior means for σ_{θ} , $\sigma_{r_{Ry\to CI}}$, and $\sigma_{r_{Ry\to OC+IL}}$. Repeated 399 simulations of 15 sets of recoveries with the actual release numbers and export levels were 400 made using Model #2 (equations 5-11) with the posterior mean values for the parameters 401 (e.g., $E[\beta_1] = -0.17$). Despite the fact that the true model did have θ as a function of exports, 402 RJMCMC typically yielded the posterior probabilities for this model in the range of 1-3%. 403 Even doubling the number of release pairs and extending the range of export levels to plus 404 or minus two standard deviations of observed values did not change these results. However, 405 if the environmental variation was artificially decreased (e.g., by an order of magnitude), 406 then RJMCMC gave posterior probabilities for the correct model (the model with exports) 407 ranging from 90 to 99%. 408

3.3 Non-hierarchical versus hierarchical

The posterior means and standard deviations of θ_t from the BHMs (#1-#6) were quite similar to the (approximate) maximum likelihood estimates, $\hat{\theta}_{2,t}$, and the standard errors (Table 2). This indicates that the influence of the prior distributions on the Bayesian results was slight. The posterior standard deviations of θ_t were generally slightly less than the standard errors, presumably a result of the "borrowing of strength" from other release-recovery data that ⁴¹⁵ informs the estimates.

⁴¹⁶ Model-based predictions of θ_t as a function of exports were quite similar for the BHM ⁴¹⁷ (equations 5-11) and the non-hierarchical model (equation (4)), but the prediction intervals ⁴¹⁸ for the BHM were considerably wider (Figure 4). The observed variation in estimates of θ_t ⁴¹⁹ (shown in Figure 4) seems more consistent with the wider BHM prediction intervals than ⁴²⁰ the non-hierarchical model intervals.

421 4 Discussion

We conclude that, for a paired release, the survival to Chipps Island of Georgiana Slough releases is considerably less than the survival to Chipps Island of Ryde releases. The ratios of recovery fractions to Chipps Island, ocean fisheries, and inland sites for Georgiana Slough releases to Ryde releases were consistently much less than 1.0 (Figure 2), and the posterior means and the maximum likelihood estimates of θ_t were at most 0.8 (Table 2). The posterior median of θ_t was 0.35 (from a model without exports, BHM #6).

Factors in addition to export that could cause lower relative survival for Georgiana 428 Slough releases include water temperature, predation, and pollution (Moyle 1994). Increasing 429 water temperatures have been associated with increasing mortality through the Delta (Baker, 430 et al. 1995). For the paired releases we have analyzed, however, water temperatures at release 431 were very similar at Ryde and Georgiana Slough within a release pair. Regarding predation, 432 Stevens (1966) found more salmon in the stomaches of striped bass located in the so-called 433 flooded islands portion of the Delta (south of the Georgiana Slough release point) relative 434 to that for the stomaches of striped bass in the Sacramento River. 435

Regarding the relationship between the relative survival and export levels, the point 436 estimates of export effects were consistently negative, and for the BHMs, the probability 437 that the effects are negative was 86 to 92%. However, the signal-to-noise ratio is low enough 438 that DIC values and posterior model probabilities indicate that the predictive ability of 439 models without exports is equivalent to that of models which include exports. Environmental 440 variation is large enough that a failure to find a stronger association could be a function 441 of inadequate sample size. Previous analyses (Newman 2008, page 72) of the relationship 442 between number of paired releases and precision of the estimated slope parameter for exports 443 showed that 100 paired releases were needed (based on $\beta_1 = -0.57$ for a logistic transformation 444 of θ) to yield a coefficient of variation of 20%. The RJMCMC analysis of simulated data 445 were consistent with those findings. 446

Exports do affect Georgiana Slough releases more than Ryde releases as the fraction of 447 Georgiana Slough releases recovered at the CVP and SWP fish salvage facilities increases 448 with increasing exports (Figure 2). The intent of the salvage operations is to increase survival 449 by relocating those fish away from the pumping facilities, and perhaps there is in fact some 450 mitigating effect. However, at the SWP facilities there is an enclosed area, Clifton Court 451 Forebay, where fish suffer mortality, due at least to predators (Gingras 1997), prior to entering 452 the salvage facilities. Experiments with marked salmon in the vicinity of the SWP fish facility 453 have yielded estimates of "pre-salvage" mortality in the range of 63-99%, with an average of 454 85% (Gingras 1997), although the quality of these estimates has been called into question 455 (Kimmerer 2008). 456

⁴⁵⁷ A tangential question is whether or not the fish facility recovery fractions are related to ⁴⁵⁸ exports or the export to flow ratio, i.e., the absolute or the relative level of exports. Over ⁴⁵⁹ the range of values observed in these studies, exports and export/flow are linearly associated

(Pearson correlation coefficient = 0.83), thus it is difficult to disentangle the effects of the 460 two factors. Deliberate fixing of export levels at varying levels of flows would be one means 461 of trying to determine if it is the absolute level or the relative level of exports that affects the 462 fraction of Georgiana Slough releases recovered at the fish salvage facilities. Current water 463 management policies and operational standards, however, make such manipulations difficult 464 to conduct. Export levels are largely determined by state and federal water project agencies 465 based on water demand, Delta conditions, Delta water quality and operational standards as 466 well as endangered species biological opinions. Due to this lack of randomization of export 467 levels and the relatively low numbers of releases, the effect of exports may be confounded 468 by other conditions that cause survival to increase or decrease. The pairing aspect of the 469 design does potentially control such confounding factors. 470

Given the low signal-to-noise ratio, instead of repeating coded-wire-tag release-recovery 471 experiments for many more years, releases of fish with acoustic tags combined with strategi-472 cally placed receivers, is recommended. Such a system could provide more precise information 473 about when and where mortality is occurring, yielding estimates of reach-specific survival 474 (Muthukumarana, Schwarz, and Swartz, 2008). How much of an effect the interior Delta 475 mortality has on the total population of Sacramento River juvenile Chinook salmon, what-476 ever the causes, depends upon the fraction of the out-migrating population that moves into 477 the interior Delta. Using coded-wire-tag release-recovery data, Kimmerer (2008) estimated 478 that the overall mortality is 10% at the highest export levels assuming a pre-salvage mortal-479 ity of 80% at the fish facilities. Pilot studies using acoustic tags have recently been carried 480 out to estimate the proportion of out-migrants entering the Delta (Perry, et al., xxxx), and 481 once this proportion is identified, the benefits of preventing fish from entering the interior 482 Delta can be estimated more accurately. 483

Table 1: Release and recovery data. R are the number released, CI and \widehat{Oc} refers to observed recoveries at Chipps Island and expanded recoveries in the ocean fisheries. \widehat{FF} refers to expanded recoveries at fish salvage facilities and \widehat{IL} are expanded inland recoveries. Ryde releases were occasionally made at Isleton (denoted by *). Exports are a three day average (cfs) for the sum of water exported from SWP and CVP and E/F is the export to flow ratio over that same period.

Table 2: Comparison of release pair-specific fitted values of θ , the ratio of the Georgiana Slough survival probability to the Ryde survival probability. The non-Bayesian, nonhierarchical results are the maximum likelihood estimates and standard errors based on the Chipps Island recoveries alone $(\hat{\theta}_1)$ and combined Chipps Island, ocean, and inland recoveries $(\hat{\theta}_2)$. The Bayesian hierarchical values are the posterior distribution means and standard deviations from the BHM with a multivariate normal distribution at Level 2 and θ modeled as a function of exports.

Table 3: Summary of Bayesian hierarchical models. Level 1 column specifies distributions (Mn = Multinomial and NB = Negative Binomial). Level 2 column has models for $\theta_{3,t}$ with N denoting Normal distribution; models for $r_{Ry\to CI,t}$ and $r_{Ry\to CI,t}$ were those shown in Equations (8) and (9) except for Multivariate Normal (MVN) and model without random effects. Level 3 column specifies prior distribution for the random effects variance; σ (U for Uniform), σ^2 (IG for Inverse Gamma), and Σ in the MVN model (IW[I,4] for Inverse Wishart with I=Identity matrix).

₅₆₇ List of Figures

568	1	Map of the Ryde and Georgiana Slough release locations and the Chipps	
569		Island recovery location.	32
570	2	Comparison of recovery fractions at Chipps Island, in the ocean fisheries, in	
571		fish facility salvage, and from inland recoveries for Georgiana Slough and Ryde	
572		releases by release pair. Straight lines on plots have slope equal to mean of	
573		the ratios of recovery fractions.	33
574	3	Expanded recovery fractions at the fish facilities near SWP and CVP plotted	
575		against the export level. Lines drawn on the plot are scatterplot smooths	
576		(dashed for Georgiana Slough; solid for Ryde)	34
577	4	Expected values, and 2.5% and 97.5% prediction intervals, for θ at different	
578		levels of exports for Bayesian Hierarchical Model $\#1$ (solid lines) and the non-	
579		hierarchical model (dashed lines) using Chipps Island recoveries and combined	
580		ocean and inland recoveries (equation (4). Circles are posterior mean fitted	
581		values for θ from the BHM and triangles are the maximum likelihood estimates	
582		based on combined Chipps Island, ocean, and inland recoveries.	35

Figure 1: Map of the Ryde and Georgiana Slough release locations and the Chipps Island recovery location.

Figure 2: Comparison of recovery fractions at Chipps Island, in the ocean fisheries, in fish facility salvage, and from inland recoveries for Georgiana Slough and Ryde releases by release pair. Straight lines on plots have slope equal to mean of the ratios of recovery fractions.

Figure 3: Expanded recovery fractions at the fish facilities near SWP and CVP plotted against the export level. Lines drawn on the plot are scatterplot smooths (dashed for Georgiana Slough; solid for Ryde).

Figure 4: Expected values, and 2.5% and 97.5% prediction intervals, for θ at different levels of exports for Bayesian Hierarchical Model #1 (solid lines) and the non-hierarchical model (dashed lines) using Chipps Island recoveries and combined ocean and inland recoveries (equation (4). Circles are posterior mean fitted values for θ from the BHM and triangles are the maximum likelihood estimates based on combined Chipps Island, ocean, and inland recoveries.
